Introduction

As part of the astounding biodiversity of terrestrial macrofungi, the boletes may undoubtedly be considered one of the most fascinating and iconic component of larger mushroom-forming fungi. Commonly known as fleshy pored mushrooms, boletes are globally distributed and belong in the monophyletic order Boletales, an extraordinary rich assemblage of polymorphic, often colorful fungi mostly characterized by stipitate-pileate boletoid and, to a lesser extent, both epigeous and belowground sequestrate, agaricoid and pleurotoid lamellate, corticioid and polyporoid habit (Binder, 1999; Binder and Hibbett, 2006; Kirk *et al.*, 2008; Watling, 2008; Nuhn *et al.*, 2013; Wu *et al.*, 2014, 2016a; He *et al.*, 2019). For over more than two centuries the identification of species of boletoid mushrooms and related groups relied exclusively on morphological, biochemical and ecological criteria. In the last thirty years, however, rapid progress of molecular phylogenetic analysis dramatically revolutionized the approach to mycological investigation through a cross-disciplinary methodology, integrating and implementing traditional research methods based on morphology, ecology and chemotaxonomy with a new generation of advanced genetic tools which played a crucial role in redefining taxonomic expertises and enabled the establishment of a more natural classification of the Boletales and its lower taxonomic ranks. Such an innovation allowed the assessment of historically established taxa and led to the uncovering of several new genera and species, therefore contributing to a better deciphering of their evolutionary affinities and biogeographic patterns worldwide.

Morphological Framework, Chemical and Ecological Features, Taxonomic Limits

Order **Boletales** E.-J. Gilbert.

Les Livres du Mycologue Tome I-IV, Tom. III: Les bolets: 83. 1931.

Typus: Boletaceae Chevallier 1828.

Although a comprehensive sharp definition of the order Boletales currently does not exist due to the prominent plasticity of physical, biochemical and ecological traits, nonetheless it is possible to define a series of common features that are shared by all or at least most of the representatives of this eclectic assemblage. The Boletales includes mushroom-forming fungi with homobasidiomycetous fruiting bodies; homoiomerous trama (hyphal tissues only) as opposed to the heteromerous trama of the Russulaceae; monomitic or occasionally dimitic or trimitic hyphal system; gymnocarpic, angiocarpic, primarily or secondarily hemiangiocarpic (velangiocarpic) or metavelangiocarpic ontogenetic development; homogeneous structure (in pileate-stipitate forms hyphae of the pileus trama confluent with and undifferentiated from those of the stipe trama); terricolous to infrequently lignicolous growth; fructifications annual, ephemeral, short-lived, easily putrescent, seldom tending to mummify in habitat (*Strobilomyces* Berk., *Cupreoboletus* Simonini, Gelardi & Vizzini), solitary, scattered to gregarious or infrequently caespitose; extremely variable polymorphism including mainly orthotropic pileate-stipitate boletoid habit, considerably less frequently orthotropic pileate-stipitate agaricoid or laterally stalked to sessile pileate-stipitate pleurotoid habit, but also secotioid or gasteroid habit, both epigeous (earthballs and earthstars) and tuberoid emergent or (sub)hypogaeal indehiscent truffle-like (false truffles) (the sequestrate morphology is the second best represented in the Boletales after the boletoid one), more rarely xylotrophic wood-decay resupinate or effuso-reflexed (corticioid or crust-like) habit and occasionally sessile polyporoid morphology, teratologic, aberrant or aborted forms (carpoforoidism) extraordinary occurring (clavarioid, coralloid and ramarioid morphologies are not at all represented in the Boletales); hymenophoral structure (spore-bearing tissue) mainly tubular-poroid (restricted to suborders Boletineae, Sclerodermatineae and Suillineae), deeply decurrent to almost free to the stipe, to a far lesser extent lamellate and in this case $\pm$ distinctly decurrent (gills attachment to the stipe other than decurrence is not observable in the Boletales) and often anastomosate, in sequestrate taxa gleba enclosed or exposed, convoluted, labyrinthine, lacunose or chambered, in corticioid taxa with a smooth, folded to meruloid or raduloid or even hydroid hymenophore, in poroid and lamellate forms the hymenophore is located on the underside of the pileus and is generally easily detachable from the pileal context above; variable dimensions of the sporophores ranging from tiny (*Gasterella* Zeller & L.B. Walker) to massive (*Phlebopus* (R. Heim) Singer); sporophores moderately to decidedly fleshy in pileate-stipitate and sequestrate forms, initially firm then softer, otherwise corky or suberous (in corticioid

genera); context white, yellowish, orange, brownish or grayish, frequently changeable (bluing, reddening, browning, blackening, etc.) by auto-oxidation; odor generally agreeable fungoid or fruity, otherwise indistinct, occasionally peculiar (sweetish, mealy, garlic or shallot-like, chicory or licorice-like, of vinyl glue, iodoform, naphthalene, vanilla, boiled milk, roasted potatoes, rotting meat, etc.); taste mild, less frequently bitterish to bitter, exceptionally peppery or sour; spore print usually olive-brown but also white, cream yellowish, yellow ochraceous, flesh pink, brownish pink, reddish, rusty brown, purplish brown, dark sooty brown to blackish; occasional formation of sclerotia (dense aggregation of fungal tissue) reported to occur in nature and cultural studies for a wide array of species belonging in a multitude of genera across the Boletales.

Anatomically, the Boletales are characterized by: mostly ellipsoid-fusiform but also elongate fusoid to cylindrical, broadly ellipsoid to ovoid or (sub)globose (more rarely with other shapes such as amygdaliform, allantoid, nephroid, etc.), usually somewhat thick-walled, hyaline to more commonly pigmented, uninucleate basidiospores with rounded, pointed to sometimes truncate distal end, with or without germ pore, smooth to less frequently with various eusporial ornamentations (obscurely striate, longitudinally costate or winged, rugulose-verrucose, pustulate-tuberculate, echinulate, cristate, reticulate-alveolate, pitted, bacillate, denticulate, etc.), ballistosporic and axially asymmetric (heterotrophic) in pileate-stipitate forms, statismosporic and axially symmetric (orthotrophic) in sequestrate representatives, with a length usually comprised in a range between 10 and 15 μm (medium-sized) but also on average smaller (small-sized, $< 10 \mu\text{m}$) (i.e., *Suillus* Gray), slightly larger (large-sized, $> 15 \mu\text{m}$) (i.e., *Leccinum* Gray) to distinctly larger (very large-sized, $> 20 \mu\text{m}$) (Gomphidiaceae), tiny (i.e. *Hygrophoropsis tapinia* Singer) to massive (i.e. *Aureoboletus projectellus* (Murrill) Halling) basidiospores also occurring, generally cyanophilic, inamyloid, dextrinoid or very rarely amyloid, sometimes with a weak metachromatic reaction; cylindrical-clavate to clavate chiasmatobasidia predominantly 4-spored but also 1-, 2- or 3-spored, very rarely 6–10-spored (in some gasteroid genera such as *Pisolithus* Alb. & Schwein., *Scleroderma* Pers., *Rhizopogon* Fr., *Alpova* C.W. Dodge, *Marthanella* States & Fogel); hymenial cystidia (cheilo- and pleurocystidia) occurring in most genera, usually ventricose-fusiform or lageniform but also differently shaped (cylindrical, clavate, capitate, mucronate, sphaeropedunculate, etc.), fertile and sterile hymenial cells (culobasidia and caulocystidia) are also present on the stipe surface of several pileate-stipitate genera, pseudocystidia occasional (*Alessioporus* Gelardi, Vizzini & Simonini, *Cupreoboletus*, some *Tylopilus* P. Karst. species, etc.); hymenophoral trama in pileate-stipitate genera $\pm$ distinctly bilaterally divergent ("*Boletus*-type", "*Phylloporus*-type" or intermediate), hardly nearly regular (referred by some European authors to as "*Mariaella*-type"); pileipellis/peridium structure in pileate-stipitate, secotioid and sequestrate forms variously arranged, usually a (ixo)trichoderm or (ixo)cutis, less frequently hymeniform (epithelium), sphaerocytic (inflated or globose cells) or compound (i.e. ixohyphoe-pithelium). Simple clamp connections absent or extremely rare in most of poroid genera (in the Boletaceae regularly and abundantly present in a handle of species only), usually present in lamellate genera (i.e. *Paxillus* Fr. and Paxillaceae as a whole). Multiple clamp connections and medallion clamp connections occurring in few genera (i.e. *Tapinella* E-J. Gilbert). Generative hyphae frequently slightly restricted at septa, hyaline to variously pigmented (epiparietal, cytoplasmatic, vacuolar pigments), thin- to more rarely thick-walled, smooth or incrustate. Hyphae of the context at the stipe base in pileate-stipitate genera mostly inamyloid, seldom distinctly amyloid (*Suillellus* Murrill, *Caloboletus* Vizzini pro parte, *Chroogomphus* (Singer) O.K. Miller, etc.). Oleiferous (thromboplerous) hyphae usually present. At the ultrastructural level the order exhibits perforate parenthesomes (wall next to the dolipore with holes).

Pigments, bioactive chemical compounds and secondary metabolites extremely heterogeneous. Different derivatives of the pulvinic acid (variegatic acid, xerocomic and isoxerocomic acid, vulpinic acid, variegatorubin, xerocomorubin, sclerocitrin, badione and norbadione, cyclovariegatin, etc.), which are responsible of the presence of yellow, red and brown pigments and also of the enzymatic bluing oxidation phenomenon evident in many boletes, occur in most of the Boletales (including the Coniophoraceae); other chemical compounds such as boviquinones (bovinone, bovilactone, helveticone and amitenone), carboxylic aromatic acids (caffeic acid, gallic acid), terphenyl quinones, atromentinic acid (atromentin, leucomentin-3, -4, -5, -6, orange-yellow flavomentin A-D, violet spiromentin A-D), polyporic acid, gomphidic acid, gomphilacton, cyclopentenones derivatives (chamonixin, involution, gyrocinin and gyroporin), phenolic metabolites (involuton), prenylated phenols (suillin, bolegrevillol and several other pigments producing grayish or brownish colorations and different oxidation reactions), prenylated benzoquinones (diboviquinone, metilenediboviquinone, tridentoquinone, rhizopogone), grevillins (grevillin A-D, anhydro-grevillin D), and many others are sporadically present in a number of different suborders, families or genera such as *Gyroporus* Quéél., *Leccinum*, *Chamonixia* Rolland, *Paxillus*, *Gyrodon* Opatowsky, *Melanogaster* Corda, *Rhizopogon*, *Suillus*, *Gomphidius* Fr., *Tapinella*, *Leucogyrophana* Pouzar, *Sutorius* Halling, Nuhn & Fechner, *Tylopilus*, etc. (see, among others, Bresinsky and Orendi, 1970; Schmitt, 1970; Bresinsky and Besl, 1979; Besl and Bresinsky, 1997; Besl et al., 1986; Gill and Steglich, 1987; Gill, 1996, 2003; Liu, 2007; Nelsen, 2010; Zhou and Liu, 2010; Velišek and Čejpek, 2011).

As far as the nutritional status is concerned, most of the poroid, lamellate and sequestrate genera in the Boletales are mutualists ectotrophically mycorrhizal (ECM) (potentially more than 90% and may represent roughly 18–25% of all ECM fungi) (Halling et al., 2007b, 2008), occasionally ericoid (restricted to the plant family Ericaceae) or tuberculate ectomycorrhizal (TECM) (this latter especially in Suillaceae and Rhizopogonaceae) with roots of a large variety of living green woody plants belonging in conifers (gymnosperms) and broadleaved trees (angiosperms) (Newman and Reddell, 1987; Halling and Mueller, 2003; Binder and Hibbett 2006; Tedersoo et al., 2010; etc.), mainly with members of the Fagaceae (*Castanea*, *Castanopsis*, *Chrysopsis*, *Cyclobalanopsis*, *Fagus*, *Lithocarpus*, *Notholithocarpus*, *Quercus*, *Trigonobalanus*), Pinaceae (*Abies*, *Cedrus*, *Keteleeria*, *Larix*, *Picea*, *Pinus*, *Pseudotsuga*, *Tsuga* and perhaps *Cathaya*), Myrtaceae (*Angophora*, *Chamelaucium*, *Corymbia*, *Eucalyptus*, *Eugenia*, *Gomidesia*, *Kunzea*, *Leptospermum*, *Lophostemon*, *Melaleuca*, *Myrtus*, *Syncarpia*, *Syzygium*, *Tristania*, *Xanthostemon*), Dipterocarpaceae (*Anisoptera*, *Dipterocarpus*, *Hopea*, *Marquesia*, *Monotes*, *Pakaraimaea*, *Parashorea*, *Pseudomonotes*, *Shorea*, *Vateria*, *Vateropsis*, *Vatica*, etc.), Casuarinaceae (*Casuarina*,

Allocasuarina), Fabaceae, including subfamilies Faboideae (*Ammopiptanthus*, *Andira*, *Millettia*, *Pterocarpus*, *Pultanea*, *Robinia*, *Sesbania*, *Swartzia*), Mimosoideae (*Acacia*, *Enterolobium*, *Inga*, *Lysiloma*, *Mimosa*, *Parkia*), Papilionoideae (*Aldinia*, *Pericopsis*) and Caesalpinioideae (viz. caesalpinoid legumes) (*Afzelia*, *Bauhinia*, *Berlinia*, *Brachystegia*, *Burkea*, *Cassia*, *Delonix*, *Dicymbe*, *Gilbertiodendron*, *Haematoxylum*, *Intsia*, *Isobertlinia*, *Julbernardia*, *Paramacrolobium*), Betulaceae (*Alnus*, *Betula*, *Carpinus*, *Corylus*, *Ostrya*), Salicaceae (*Populus*, *Salix*), Ericaceae (*Andromeda*, *Arbutus*, *Arctostaphylos*, *Comarostaphylis*, *Erica*, *Pieris*, *Rhododendron*), Cistaceae (*Cistus*, *Helianthemum*, *Halimium*, *Hudsonia*), Nothofagaceae (*Nothofagus*), Nyctaginaceae (*Guapira*, *Neea*, *Pisonia*), Polygonaceae (*Coccoloba*, *Gymnopodium*), Uapacaceae (*Uapaca*), just to name a few. Furthermore, the orchid genus *Vanilla* should be added to the list as it has been found for the first time to form symbiosis with a representative of the Boletales (González-Chávez *et al.*, 2018). In native and alien naturalized ectotrophic forests, woodlands and scrublands dominated by plants of these families, boletes typically constitute an integral part of the mycota during the rainy season. Additionally, many species of *Suillus*, *Scleroderma*, *Pisolithus*, *Rhizopogon* and other notoriously ectotrophic genera are commonly used as biotechnology tools in pure-culture synthesis and in forestry (mycosilviculture) as optimal candidates for ECM mycelial inoculum to enhance seedlings establishment and plant growth through improved water and nutrient uptake (by enlarging root's effective absorptive area), increased tolerance to drought stress, the ability of linking plant roots for a profitable interplant exchange of substances and therefore to ensure a better establishing of artificial plantations in reforestation programmes or vegetational restoration plans and of outplanted landscape trees both in pristine and disturbed or otherwise depauperate, contaminated or degraded ecosystems (Singer, 1986; Molina and Trappe, 1994; Agerer, 2006; Watling, 2008; etc.). Members of the suborder Suillineae are almost exclusively obligate symbionts of the Pinaceae, however, the Gomphidiaceae can establish, although infrequently, ordinary ECM symbiosis with Pinaceae but they are also able to facultatively parasitize rhizomorphs and ectomycorrhizas of the Suillaceae and Rhizopogonaceae, as already noted by Miller (1964) and Smith and Zeller (1966) and subsequently confirmed by several authors (Singer, 1986; Agerer, 1990, 1991, 1996, 2002, 2006; Agerer *et al.*, 1996; Olsson *et al.*, 2000; Binder and Hibbett, 2006; Kirk *et al.*, 2008; Watling, 2008; Li *et al.*, 2009; McLaughlin and Spatafora, 2014; etc.). It is therefore possible to define the Gomphidiaceae as “episymbionts” engaging a three- (four-)way interaction between the tree hosts and other representatives of the Suillineae (Olsson *et al.*, 2000; Knudsen and Taylor, 2008). Nonetheless, the exact biological nature, myco-parasitism dynamics and the degree of specificity among these families have not yet been clarified (Li *et al.*, 2009; Scambler *et al.*, 2018) and further studies are urgently required to assess their multipartite relationships (Agerer, 2006).

A few genera in the Boletaceae are selective species-specific mycoparasites (*Chalciporus* Bataille, *Pseudoboletus* Šutara, *Buchwaldoboletus* Pilát pro parte) of some ECM genera in the Boletales or other Basidiomycetes (*Amanita* Pers. spp., *Phaeolus Schweinitzii* (Fr.) Pat., etc.). Some species belonging in *Phlebobius* (Boletinellaceae) appear to be entomosymbiotic or symbiotic/parasitic in relation to the root infection of numerous trees, such as in the case of the plant genus *Citrus* (Rutaceae) in Brazil, provoked by the insect *Pseudococcus comstocki* and by at least 13 other soil mealy bugs (belonging mostly in Pseudococcidae but also in Monophlebidae and Eriococcidae) brought by ant species (i.e., *Solenopsis moelleri* Forel). *Phlebobius* species establish a unique mutually beneficial tripartite nutritional relationship through the formation of fungus-insect galls (also called “crypta”) on the roots of the host plants (Singer, 1946, 1986; Singer and Digilio, 1957; Singer *et al.*, 1983; Binder and Bresinsky, 2002b; Watling, 2008; Tedersoo *et al.*, 2010; Pham *et al.*, 2012; Zhang *et al.*, 2015; Fang *et al.*, 2020; Yu *et al.*, 2020; Raghoonundon *et al.*, 2021). Fang *et al.* (2020) stressed that *P. portentosus* (Berkeley & Broome) Boedijn forms a symbiotic association with mealy bugs, whose galls afford a safe and comfortable shelter for the insects, which in turn provide essential nutrients for the mycelial growth of fungal organism with the secreted honeydew (rich in amino acids and sugars) and, according to Mei *et al.* (2021), possibly also other metabolites or necromass. In line with the trophic behavior of congeneric species, the recently described *Phlebobius roseus* M. Yang, C.-Y. Liu & Y. Wang has been observed to form a symbiotic association with the insect *Coccus hesperidum* L., developing fungus-insect galls on roots of an agriculturally exploited loquat trees orchard (*Eryobotria japonica* (Thunb.) Lindl.) in south-western China (Mei *et al.*, 2021). Similarly, in the closely related genus *Boletinellus* Murrill (Boletinellaceae), the so-called “ash bolete” *B. meruliioides* (Schwein.) Murrill, is known to be able to establish a three-way association with *Fraxinus* spp. (Oleaceae) and an arthropod, *Prociphilus fraxinifolii* Riley (aphids), which is nested in the sclerotia (or fungal-insect galls) produced by the mushroom itself, receiving protection from ants and centipedes and probably returning to fungal organism nutrients in form of honeydew (Brundrett and Kendrick, 1987; Gruhn *et al.*, 1992; Nagasawa, 2001; Binder and Bresinsky, 2002b; Wang and Qiu, 2006; Tedersoo *et al.*, 2010; Wilson *et al.*, 2012; Nuhn, 2016). The nature of ecological and physiological interactions among these organisms certainly deserves further investigation. Anyway, based on available knowledge there would appear to be no parasitic member of the Boletales being strictly pathogen of arboreous plants.

A relatively low percentage of saprotrophic taxa are found either on soil or on woody substrates. All saproxylic wood-rotting members of the Boletales inhabit decayed stumps, debris, fallen twigs or branches and dead standing trees preferably of conifers and exclusively produce Coniophoraceae-type brown rot, dry rot or brown cubical heart rot (named from the typical fracturing of wood in orthogonal structures) (white rot and soft rot lignicolous decomposers are not at all present in the Boletales), leading to the rapid oxidation of cellulose through the Fenton's mechanism. Corticioid genera (*Coniophora* DC., *Serpula* (Pers.) Gray, *Leucogyrophana* Pouzar, etc.), which are among the most dangerous wood-destroying fungi, can also develop and extend upon handmade building structures such as wooden timber, plaster, porous bricks and stones (Gilbertson, 1981; Kämmerer *et al.*, 1985; Hibbett and Binder, 2002; Binder *et al.*, 2005; Binder and Hibbett, 2006; Watling, 2008; Hyde *et al.*, 2018; Zmitrovich *et al.*, 2019b). However, as a general rule the occurrence of basidiomes in elevated positions on woody substrata is not necessarily a prerequisite of saprotrophic nutritional mode (Rayner *et al.*, 1985; Henkel *et al.*, 2000). Examples of lignicolous growth of ECM pileate-stipitate Boletaceae have been reported from all around the world and this fruiting behavior could be explained as a

strategy for enhancing spore dispersal, for selective foraging of N in rotting wood, or otherwise as a behavior to preserve basidiomata from becoming water-soaked under wet conditions (Weber and Sundman, 1986; Jurgensen *et al.*, 1987; Henkel *et al.*, 2000, 2012; Lindahl and Tunlid, 2015; Farid *et al.*, 2018).

Ectomycorrhizal families Boletaceae, Gyroporaceae, Melanogastraceae, Paxillaceae, Rhizopogonaceae, Sclerodermataceae and Suillaceae share the most advanced type of rhizomorphs (boletoid rhizomorphs) and the ECM mantle is plectenchymatous (consisting of interwoven filamentous hyphae), frequently with a ring-like pattern; genera in the Gomphidiaceae exhibit amyloid ECM (Agerer, 1999, 2006).

Last but not the least, another unifying trait of the Boletales is indirectly represented by pathogen organisms; members of this order are often infected and colonized by some species of the ascomycete genus *Hypomyces* (Fr.) Tul. (teleomorph) (anamorph *Sepedonium* Link), especially *H. chrysospermus* Tulasne & C. Tulasne and related taxa, suggesting a certain degree of co-evolution and specialization between parasite and host species (Rogerson and Samuels, 1989; Sahr *et al.*, 1999; Douhan and Rizzo, 2003; McLaughlin and Spatafora, 2014).

Brief Historical Overview and Current State of Knowledge

The order Boletales, corresponding to the tribe Bolétés as circumscribed by Patouillard (1900), was first formally settled by Gilbert (1931), whose work laid the foundation for the modern study of boletoid mushrooms. Two suborders, namely Boletineae (including 9 genera with smooth spores, viz. *Boletinellus*, *Boletinus* Kalchbr. (= *Suillus*), *Boletus*, *Gyrodon*, *Ixocomus* Quél. (= *Suillus*), *Krombholzia* P. Karst. (= *Leccinum*), *Phylloporus* Quél., *Porphyrellus* E.-J. Gilbert and *Xerocomus* Quél.) and Strobilomycetinae (including taxa with ornamented spores, viz. *Strobilomyces* and *Boletellus* Murrill) were also established by the French author to place European and American boletes. For a long time, however, the classification of boletes and allied groups has been particularly instable, the order Boletales was largely disregarded (Horak, 1968) or not unanimously conceived by posterior authors and its circumscribing boundaries as well as those of lower taxonomic ranks (suborders, families, genera, etc.) remained controversial and unclear due to strongly divergent opinions as to how delimiting lines ought to be drawn for this group. Kühner and Romagnesi (1953) divided the European boletes into two informal groups, namely “bolétacées lamellées” (lamellate boletes) (encompassing *Phylloporus*, *Gomphidius* and *Paxillus*) and “bolétacées porées” (poroid boletes) and assigned the poroid boletes to a single genus *Boletus* divided into ten subgenera (*Strobilomyces*, *Gyroporus*, *Krombholzia*, *Tylopilus*, *Tubiporus* P. Karst. (= *Boletus*), *Porphyrellus*, *Xerocomus*, *Ixocomus*, *Boletinus*, *Gyrodon*). Hongo (1960) accounted four families (Paxillaceae, Gomphidiaceae, Boletaceae and Strobilomycetaceae) in the order Agaricales to accommodate Japanese boletes and closely related taxa. No mention was done by Watling (1970) about the order they belong in, but he grouped British boletoid mushrooms and allies into three families by recognizing only a limited number of genera: Boletaceae (including *Aureoboletus* Pouzar, *Boletinus*, *Boletus*, *Gyroporus*, *Leccinum*, *Porphyrellus*, *Strobilomyces*, *Suillus*, *Tylopilus* and *Uloporus* Quél. (= *Gyrodon* Opat.)), Gomphidiaceae (*Chroogomphus* and *Gomphidius*) and Paxillaceae (*Paxillus* and *Phylloporus*). Shortly after Smith and Thiers (1971), following Watling’s perspective, proposed a single family Boletaceae for the fleshy pored mushrooms of Michigan (USA). Corner (1972b), based on the enormous diversity of south-eastern Asian boletes (with a special focus on the Indo-Malayan region), preferred to maintain a taxonomic conservative approach and recognized only four genera, specifically *Boletus* (with a number of discrete subgenera), *Gyroporus*, *Heimiella* Boedijn (now *Heimioporus* E. Horak) and *Strobilomyces*. Two years later Pilát and Dermek (1974), in their monographic treatment on central European boletes, disposed poroid mushrooms and relatives into a family Gomphidiaceae (including *Gomphidius*) and a widely delimited family Boletaceae (including 16 boletoid genera and the lamellate *Phylloporus*), which was in turn subdivided into two subfamilies, Strobilomycetoideae (including *Strobilomyces* and *Porphyrellus*, i.e. taxa with ornamented spores or with a purplish brown spore print) and Boletoidae (including all remaining genera with smooth basidiospores). Rolf Singer, in his numerous publications and especially in his fourth and last edition of a comprehensive mycological milestone such as “The Agaricales in modern taxonomy” (Singer, 1986), did not recognize the Boletales as an autonomous consortium standing by its own, instead he assigned 34 genera worldwide to the suborder Boletineae within the order Agaricales, sorting them out in three different families: Paxillaceae, Gomphidiaceae and a broadly conceived family Boletaceae (this latter divided in turn into subfamilies Gyroporoideae, Gyrodontoideae, Suilloideae, Strobilomycetoideae, Boletoidae and Xerocomoideae), which subsumed genera that are presently accommodated into five different families belonging in three separate suborders (see below). Prior to Singer and conversely to his systematic framework, Kühner (1977) recognized the order Boletales and allocated the genera *Strobilomyces*, *Gyroporus*, *Boletus* (divided into subgenera *Gyrodon*, *Phylloporus*, *Xerocomus*, *Boletus*, *Tylopilus*, *Porphyrellus* and *Leccinum*), *Suillus* (including *Suillus* and *Boletinus*) and *Gomphidius* (including subgenera *Gomphidius* and *Chroogomphus*) to a sole family Boletaceae and the genera *Hygrophoropsis* (J. Schröter) Maire ex Martin-Sans and *Paxillus* (including subgenera *Paxillus* and *Tapinella*) to the family Paxillaceae. Pegler and Young (1981) maintained and rearranged the Boletales on a global scale based primarily on basidiospore morphology and distributed 35 genera within six families, namely Boletaceae, Gomphidiaceae, Gyrodontaceae, Paxillaceae, Strobilomycetaceae and Xerocomaceae. Likewise Moser (1983) accepted the order Boletales as distinct from the Agaricales and listed 21 European genera distributed in four different families (Strobilomycetaceae, Boletaceae, Paxillaceae and Gomphidiaceae).

A large number of regional mycological floras, comprehensive monographic treatises, color atlas, reference books, checklists and popular field guides have dealt with fleshy pored mushrooms and related lamellate, sequestrate and corticioid taxa over the past two centuries (Fries, 1821, 1838; Frost, 1874; Quélet, 1888; Peck, 1889; Bataille, 1908; Smotlacha, 1912; Murrill, 1914; Coker and Couch, 1928; Coker and Beers, 1943; Singer, 1945, 1946, 1947, 1965, 1967, 1986; Chiu, 1948, 1957; Heinemann, 1951;

Imazeki, 1952; Singer and Digilio, 1957, 1964; Pilát, 1958; Hongo, 1960, 1973; McNabb, 1967, 1968, 1969; Horak, 1968, 2011; Corner, 1971a,b, 1972b; Snell and Dick, 1970; Smith and Thiers, 1971; Pilát and Dermek, 1974; Kühner, 1977; Vasiljeva, 1978; Tai, 1979; Wolfe, 1980; Pegler and Young, 1981; Moser, 1983; Singer *et al.*, 1983, 1990, 1991, 1992; Alessio, 1985; Garrido, 1988; Imazeki *et al.*, 1988; Watling and Hollands, 1990; Watling and Turnbull, 1992, 1994; Both, 1993; Lakhanpal, 1996; Nagasawa, 1997; Watling and de Meijer, 1997; Ginns, 1998; Watling and Li, 1999; Bessette *et al.*, 2000; Li and Song, 2000; Montecchi and Sarasini, 2000; Lannoy and Estadès, 2001; Ladurner and Simonini, 2003; Muñoz, 2005; Šutara, 2005, 2008; Zang, 2006; Klofac, 2007; Ortiz-Santana *et al.*, 2007; Knudsen and Taylor, 2008; Bernicchia and Gorjón, 2010; Zang *et al.*, 2013; etc.), however, the approach to the study of bolete taxonomy has radically changed with the increasing availability of molecular genetic investigation applied to the study of basidiomycetes, casting doubts on the validity of relying solely on visible features for identification and highlighting the necessity to clarify the discrepancies between genetic and morphological criteria.

The order Boletales is one of the most diverse and widespread groups of Basidiomycetes. Unlike R. Heim's hypothesis indicating a polyphyletic origin of the boletes (Singer, 1981), the order Boletales is definitely a monophyletic lineage recovered within the subclass Agaricomycetidae, superorder Agaricanae, alongside and in a close proximity to five other orders namely Agaricales, Amylocorticiales, Stereopsidales, Atheliales and Lepidostromatales, the latter two being sister and closer to the Boletales, and together being sister to the remaining aforementioned orders (Bruns *et al.*, 1998; Kretzer and Bruns, 1999; Jarosch, 2001; Binder and Bresinsky, 2002b; Larsson *et al.*, 2004; Binder *et al.*, 2005, 2010; Binder and Hibbett, 2006; Matheny *et al.*, 2007; He *et al.*, 2019; Varga *et al.*, 2019; Sánchez-García *et al.*, 2020).

At present, according to the most recent molecular phylogenetic inference, the order Boletales is subdivided into 5 suborders, 18 families and some 150 accepted genera (including the sclerodermatoid fossil genus *Palaeogaster* Poinar, Alfredo & Baseia, see Poinar *et al.*, 2014), containing approximately 2194 species worldwide (this number accounts officially described species as well as those molecularly detected but not yet formally named) (Pers. Obs.), far beyond the 1316 species estimated by Kirk *et al.* (2008) but roughly similar to the number (2022) indicated by He *et al.* (2019). The backbone suprageneric arrangement of the Boletales is summarized up as follows:

- suborder Tapinellineae Agerer
 - a. family Tapinellaceae C. Hahn
- suborder Coniophorineae Agerer & C. Hahn
 - a. family Coniophoraceae Ulbrich
 - b. family Hygrophoropsidaceae Kühner
- suborder Suillineae Besl & Bresinsky
 - a. family Gomphidiaceae R. Maire ex Jülich
 - b. family Rhizopogonaceae Gäumann & C.W. Dodge
 - c. family Suillaceae (Singer) Besl & Bresinsky
 - d. family Truncocolumellaceae Agerer
- suborder Sclerodermatineae Manfr. Binder & Bresinsky
 - a. family Boletinellaceae P.M. Kirk, P.F. Cannon & J.C. David
 - b. family Calostomataceae E. Fischer
 - c. family Diplocystidiaceae Kreisel
 - d. family Gyroporaceae (Singer) Manfr. Binder & Bresinsky
 - e. family Pisolithaceae Ulbrich
 - f. family Sclerodermataceae Corda
- suborder Boletineae Rea emend. E.-J. Gilbert
 - a. family Paxillaceae Lotsy
 - b. family Boletaceae Chevallier
- *incertae sedis*
 - a. family Gasterellaceae Zeller
 - b. family Serpulaceae Jarosch & Bresinsky

Kirk *et al.* (2008) and He *et al.* (2019) merged the families Pisolithaceae and Truncocolumellaceae with the Sclerodermataceae and Suillaceae, respectively. In the present account, however, we retain these two families at their autonomous hierarchic rank following Binder and Hibbett (2006) and Wu *et al.* (2020). Moreover, the suborder Sclerodermatineae has been differently interpreted by Moreau *et al.* (2013a). Based on the assumption that gasteroid genera in the Sclerodermatineae formed a unique evolutionary line based on similar anatomical features, they proposed, following Agerer (1999), to replace a systematic arrangement of suborder

Sclerodermatineae including multiple families with a single family Sclerodermataceae to be subdivided into four different subfamilies namely Boletinelloideae, Gyroporoideae, Sclerodermoideae and Calostomatoideae.

Suborders Tapinellineae and Coniophorineae occupy the basal position in the Boletales, representing the earliest evolutionary diverging lineages; they mostly consist of lignicolous corticioid, pleurotoid and polyporoid genera. In addition, the Tapinellineae form a sister group to all remaining suborders (Binder *et al.*, 2010). In the suborder Suillineae boletoid and agaricoid taxa are found in the Suillaceae and Gomphidiaceae, respectively, while the Rhizopogonaceae and Truncocolumellaceae harbor sequestrate species. The suborder Sclerodermatineae mostly comprises epigeous gasteroid genera distributed among Calostomataceae, Diplocystidiaceae, Pisolithaceae and Sclerodermataceae, with boletoid genera restricted to Boletinellaceae and Gyroporaceae. However, this suborder has been resolved as paraphyletic by Sato and Toju (2019) being formed by the sister lineages Sclerodermatineae s.str. and Boletinellaceae. In addition the Sclerodermatineae are strongly supported as sister of the clade including Boletinellaceae, Paxillaceae and Boletaceae (Sato and Toju, 2019). Within suborder Boletineae, the Paxillaceae contains a mixed assemblage of boletoid, agaricoid, hypogeous sequestrate, polyporoid and perhaps corticioid taxa (although the phylogenetic placement of *Hydnomerulius* Jarosch & Besl currently remains uncertain), whereas the hyperdiverse Boletaceae represents the core lineage in the Boletales and contains the bulk of boletoid mushrooms, embracing at present roughly 1427 species distributed in 95 different genera. Sequestrate members are well-represented in this family but it is mainly consisting of boletoid genera with a few additional lamellate representatives. Based on multilocus phylogenetic analysis, Wu *et al.* (2014) recovered five major subclades in the Boletaceae, four out of which have been formally introduced as monophyletic subfamilies Boletioideae, Xerocomoideae, Leccinoideae, Zangioideae and Chalciporoideae, this latter along with the genus *Pseudoboletus* occupying the basal position in the family and being sister to all other infrafamilial groups; in particular the *Chalciporus*/*Rubinoboletus* and *Buchwaldoboletus* lineages represent the primeval, most archaic branch in the Boletaceae and have a position even more basal than that of *Pseudoboletus* (Binder and Hibbett, 2006; Nuhn *et al.*, 2013; Wu *et al.*, 2014, 2016a,b; Sato and Toju, 2019). The fifth subclade, that still remains unresolved, has provisionally been named “Pulveroboletus group” (Wu *et al.*, 2014).

The number of newly defined (or resurrected) genera and species recognized in the Boletaceae has steadily increased over the last two decades and are still being discovered as a result of the advancement of molecular techniques (Binder and Bresinsky, 2002a; Bresinsky and Besl, 2003; Halling *et al.*, 2007a, 2012a,b; Desjardin *et al.*, 2008, 2009; Šutara, 2008; Orihara *et al.*, 2010, 2016b; Li *et al.*, 2011b, 2014b; Lebel *et al.*, 2012; Zeng *et al.*, 2012, 2014; Hosen *et al.*, 2013; Trappe *et al.*, 2013; Arora and Frank, 2014; Gelardi *et al.*, 2014, 2015a, b; Vizzini, 2014a,b,c,d,e,f, 2015; Zhao *et al.*, 2014; Zhu *et al.*, 2014, 2015; Assyov *et al.*, 2015; Smith *et al.*, 2015; Castellano *et al.*, 2016; Henkel *et al.*, 2016; Wu *et al.*, 2016a,b, 2018; Orihara and Smith, 2017; Crous *et al.*, 2018, 2020; Farid *et al.*, 2018; Parihar *et al.*, 2018; Zhang and Li, 2018; Chai *et al.*, 2019; Khmel'nitsky *et al.*, 2019; Vadthanarat *et al.*, 2019a; Sulzbacher *et al.*, 2020) and several traditionally established genera which were inferred to be unwieldy and polyphyletic (*Boletellus*, *Boletus* Fr., *Leccinum*, *Pulveroboletus* Murrill, *Tylopilus*, *Xerocomus*, etc.) have been thoroughly re-organized by means of morphological, ecological and extensive DNA sequencing (Peintner *et al.*, 2003; den Bakker and Noordeloos, 2005; Taylor *et al.*, 2006; Dentinger *et al.*, 2010; Feng *et al.*, 2012; Cui *et al.*, 2015; Halling *et al.*, 2015; Wu *et al.*, 2016a; Gelardi *et al.*, 2019) (Table 1). However, as opposed to the current trend of proliferation of new genera, an alternative, much broader and conservative approach to the systematic of the Boletaceae has most recently been proposed by Kuo and Ortiz-Santana (2020). They have suggested to re-arrange this family by lumping single taxonomic units into larger groupings in order to facilitate the understanding of their respective phylogenetic relationships. Notably, they collapsed all genera of the core leccinoid clade into a very broadly circumscribed genus *Leccinum* based on a purported paraphyly of its representatives as previously suggested by den Bakker and Noordeloos (2005), Lebel *et al.* (2012) and Wu *et al.* (2014).

Anyway, as a result of the ongoing discoveries, the most recently compiled monographic works, dichotomous keys and mycological divulgative books are gradually starting to metabolize the lately proposed molecular phylogenetic novelties (Bessette *et al.*, 2016, 2019; Mikšík 2017; Noordeloos *et al.*, 2018; Klofac and Krisai-Greilhuber, 2020).

Origins, Diversification and Historical Evolutionary Dynamics

The monophyly of the order Boletales is strongly supported by molecular phylogenetic analysis based on sequences of barcode genes, consequently all taxa belonging in this order share a single, common origin (Binder *et al.*, 1997; Bruns *et al.*, 1998; Kretzer and Bruns, 1999; Jarosch, 2001; Binder and Bresinsky, 2002b; Eberhardt and Taylor, 2005; Binder and Hibbett, 2006; Zhao *et al.*, 2017; Sato and Toju, 2019). The accuracy of calibrated molecular clock models allowed to infer the origin of the Boletales in the Mesozoic Era, Upper Permian to Lower Cretaceous, more or less overlapping in age with the Pinaceae or a little later but pre-dating the formation of rosids (Malloch *et al.*, 1980; LePage, 2003; Hibbett and Matheny, 2009; Dentinger *et al.*, 2010; García-Sandoval *et al.*, 2011; Wilson *et al.*, 2012; Han *et al.*, 2018). However, the earliest diversification of the Boletales from their close relatives in the Agaricomycetes has been differently estimated in terms of million years ago (mya) by various authors (Table 2).

The most recent estimate using six fossil calibration dates the origin of the Boletales back to 151 mya (Sánchez-García *et al.*, 2020). The same authors estimated the origin of the Boletales to be older than that of the Agaricales (134 mya), roughly contemporaneous to the Amylocorticiales (144 mya) and Atheliales (144 mya) but younger than Polyporales (193 mya) and Phallales (203 mya) and much younger than Russulales (236 mya) and Cantharellales (309 mya) (Sánchez-García *et al.*, 2020). In sharp contrast, Varga *et al.* (2019) inferred the Agaricales to be significantly older (173 mya) than the Boletales and this latter to be slightly older than the Russulales.

Within the Boletales, the suborder Boletineae presently concentrates the greatest number of boletoid genera and likely originated in the Upper Cretaceous, around 91–71 mya (range comprised between 133 and 41 mya) but was supposed to radiate rapidly, leaving few genetic signatures at the time of its divergence from a common ancestor (Dentinger *et al.*, 2010). The Boletineae are monophyletic and strongly supported by molecular analysis, however, their taxonomic and phylogenetic backbone still remains scarcely resolved (Binder and Hibbett, 2006; Halling *et al.*, 2007a, 2012a, 2015; Nuhn *et al.*, 2013; Wu *et al.*, 2014,

Table 2 Origin of the order Boletales as inferred in recently published works. Extreme values in parenthesis indicate the time range whereas average values are in bold face. Dating estimations are expressed in million years ago (mya)

Estimated divergence dates (mya)	Reference(s)

2016a; Sato and Toju, 2019). Similarly, the suborder Sclerodermatinae originated in eastern and south-eastern Asia and North America in the Upper Cretaceous, in a period comprised between (115) 82–80 (54) mya, while the diversification of the “core Sclerodermatinae” (including major gasteroid genera such as *Scleroderma*, *Pisolithus* and *Astraeus* Morgan) was inferred between the middle and Early Cenozoic (Wilson *et al.*, 2012). According to Wilson *et al.* (2012), the suborder Suillineae originated in the Early Cenozoic, some (64) 56–53 (50) mya. Recent molecular studies placed the family Serpulaceae close to the suborder Tapinellinae which constitutes its sister group and from which it separated during the Upper Cretaceous around 64 mya, diverging from a common ancestor established in the temperate belt of western North America (Skrede *et al.*, 2011). In the Boletaceae, the diversification of porcini mushrooms (*Boletus* s.str.) from allied taxa has been estimated in the Late Eocene, at the beginning of Cenozoic or Tertiary Era, orientatively between 44 and 34 mya (Dentinger *et al.*, 2010), or even earlier in Late Cretaceous (109) 77 (46) mya (Feng *et al.*, 2012).

From an evolutionary viewpoint based on ancestral state reconstruction, advanced pileate-stipitate forms in the Agaricomycetes and particularly in the Agaricomycetidae would have arisen in the Lower Jurassic (180–170 mya). They are correlated with increased diversification rates when compared to non-pileate forms and likely derived from plesiomorphic saprotrophic resupinate ancestors producing a white rot (Hibbett and Matheny, 2009; Binder *et al.*, 2010; Varga *et al.*, 2019; Sánchez-García *et al.*, 2020). Cifelloid, clavarioid/ramarioid and sequestrate (including secotoid) forms would appear to be even more recent (Varga *et al.*, 2019). Likewise the order Boletales, conversely to earlier assumptions by Hibbett *et al.* (1997) would not descend from a boletoid ancestor but rather from a saprotrophic resupinate or more probably polyporoid mushroom-forming fungus producing a brown rot on conifer decayed wood (Binder and Hibbett, 2001, 2006; Larsson *et al.*, 2004; Eberhardt and Taylor, 2005; Watling, 2008). As stated above, suborders Tapinellinae and Coniophorineae occupy the basal position and represent the ancestral state in the Boletales, harboring taxa morphologically most similar to the shape of the purported common ancestor of the Boletales (Eberhardt and Taylor, 2005; Sato and Toju, 2019). Therefore, Petersen's theory (Petersen, 1971a,b) appears to be wrong in suggesting a gomphoid mushroom as the forefather of the Boletales based on similarities in basidiospore ornamentation and some other morphological features of *Gomphus* Pers. with certain boletoid genera such as *Austroboletus* (Corner) Wolfe and *Strobilomyces* (see also Pegler and Young, 1981).

Resupinate lignicolous forms would appear to represent the most recent common ancestors of the families Serpulaceae, Hygrophoropsidiaceae and the suborder Coniophorineae. Moreover pileate-stipitate fungi with lamellate hymenophore in the basal lineages such as *Tapinella* and *Hygrophoropsis* would have evolved various times from resupinate ancestors whereas the most recent precursor of the suborders Sclerodermatinae and particularly Boletineae should be a pileate-stipitate form with tubular hymenophore and smooth basidiospores from which both lamellate and gasteroid forms might have later derived (Hibbett *et al.*, 1997; Binder *et al.*, 2005, 2010; Binder and Hibbett, 2006; McLaughlin and Spatafora, 2014; Wu *et al.*, 2014). As a demonstrative example, *Sedecula pulvinata* Zeller is the only known sequestrate hypogeous species in the Coniophoraceae and might have evolved from resupinate forms in this same family. Furthermore, this monotypic genus constitutes one of the earliest non-resupinate taxa in the evolutionary history of the Boletales (Trappe *et al.*, 2015) and would appear to be the only sequestrate member of the boletales with a confirmed non-ectomycorrhizal trophic mode.

Beside pileate-stipitate genera, both epigeous and hypogeous sequestrate taxa constitute a major presence within the order Boletales and their spore discharge, being non-active, involves weathering (air, rainfall) or animal consumption (mammals, reptiles, birds and invertebrates such as worms, centipedes, slugs, etc.) for dispersal in the environment. Far before the development of molecular phylogenetic analysis several authors had already speculated on strict evolutionary relationships between gasteroid and boletoid genera (Malençon, 1931; Smith and Zeller, 1966; Heim, 1971; Thiers, 1971, 1984), but it was generally supposed that resupinate taxa represented a valid taxonomic unit (Gasteromycetes) based on the assumption that forcible spore discharge was rarely lost during the evolutionary history of basidiomycetes (Coker and Couch, 1928), or that the secotoid/gasteroid state was ancestral and therefore primitive with respect to the pileate-stipitate morphology (Singer, 1981). By converse, modern phylogenetic approaches have definitely rejected these scenarios and reinforced theories based on some previous morphological and chemo-taxonomical studies (Heim, 1971; Moore, 1998; Reijnders, 2000), that sequestrate fungi (including hypogeous taxa) are polyphyletic, generally young (50–4 mya) and evolved independently several times in numerous fungal

lineages in the Agaricomycetes starting from different morphologies and following a process defined as gasteromycetation (Bruns *et al.*, 1989; Kendrick, 1992; Bougher *et al.*, 1993; Hibbett *et al.*, 1994, 1997; Mueller and Pine, 1994; Miller *et al.*, 2000; Peintner *et al.*, 2001; Giachini *et al.*, 2006; Trappe *et al.*, 2009; Gube and Dorfelt, 2012; Lebel and Syme, 2012; Lebel *et al.*, 2015; Ge and Smith, 2013; Han *et al.*, 2017; Sánchez-García *et al.*, 2020). The order Boletales makes no exception and gasteroid genera have been inferred to have derived from both boletoid and agaricoid forms (Kretzer and Bruns, 1997; Bruns *et al.*, 1998; Miller and Aime, 2001; Binder and Hibbett, 2006; Nuhn *et al.*, 2013; Wu *et al.*, 2014; Smith *et al.*, 2015). The sequestrate hypogeous *Chamonixia*, *Octaviania* Vittadini, *Rosbeevera* T. Lebel & Orihara and *Turmalinea* Orihara & N. Maekawa would have transformed independently from different boletoid ancestors in the leccinoid clade (subfamily Leccinoideae) (Binder, 1999; den Bakker and Noordeloos, 2005; Orihara *et al.*, 2016b). Moreover, subfamily Leccinoideae appears to be the richest in number of gasteroid representatives within the Boletaceae (Orihara *et al.*, 2016b). These results are consistent with the surmise that the common ancestor of the suborders Boletineae and Sclerodermatineae must have been a boletoid form (Binder and Hibbett, 2006). In the Boletales only few genera are entirely secotioid, such as the monospecific *Singeromyces* M.M. Moser and *Gymnogaster* J.W. Cribb and the polyphyletic *Gastroboletus* Lohwag, whereas a number of secotioid or even understorey sequestrate species are nested in predominantly boletoid genera, namely *Afroboletus* Pegler & T.W.K. Young, *Boletus* s. str., *Fistulinella* Hennings, *Leccinellum* Bresinsky & Manfr. Binder, *Neoboletus* Gelardi, Simonini & Vizzini and *Xerocomellus* Šutara (Trappe *et al.*, 2003; Dentinger *et al.*, 2010; Wu *et al.*, 2016a,b; Han *et al.*, 2017; Smith *et al.*, 2018; Frank *et al.*, 2020). Similarly, secotioid taxa are also occurring in the genera *Suillus* (Suillaceae) and *Chroogomphus* (Gomphidiaceae) (Baura *et al.*, 1992; Kretzer and Bruns, 1997; Miller and Aime, 2001; Miller, 2003; Nguyen *et al.*, 2017). Assuming Thier's hypothesis (Thiers, 1984) as true, in the family Paxillaceae (in relation to the presence of thromboplerous hyphae in the agaricoid genus *Paxillus* and their seemingly gradual disappearance in the sequestrate *Alpova*) and in the suborder Sclerodermatineae, gasteroid taxa would have evolved from a complex of pileate-stipitate taxa with a tubulate hymenophore consisting of *Boletinellus*, *Phlebopus* and *Gyroporus*, losing at first their ability to forcible discharge spores in the environment in favor of a non-active spore dispersal and subsequently reducing their stipe progressively (Reijnders, 2000; Binder and Bresinsky, 2002b; Moreau *et al.*, 2013b). Such an evolutionary process thus entails a hypothetical reversal from gasteroid to non-gasteroid forms as highly unlikely (Sánchez-García *et al.*, 2020) since it would involve a return to the complex mechanism of forcible spore discharge of ballistospore fungi, ultimately supporting the general assumption that the loss of ballistospory was irreversible (Savile, 1955; Thiers, 1984; Bruns *et al.*, 1989; Mueller and Pine, 1994; Hibbett *et al.*, 1997; Hibbett, 2004; Wilson *et al.*, 2011; Halling *et al.*, 2012b). A similar scenario may be virtually extended to all secotioid/gasteroid fungi (Lebel *et al.*, 2012), such as the polyphyletic *Gastroboletus* (Smith and Zeller, 1966), *Royoungia* Castellano, Trappe & Malajczuk and *Truncocolumella* Zeller (Castellano *et al.*, 1992) which would not at all represent the ancestral archetypes of boletoid mushrooms but rather aberrant phenotypes (or mutations) of these latter, characterized by limited environmental adaptation and reduced or absent reproductive ability, therefore exposed to disadvantages and vulnerability in natural selection and more susceptible to an elevated risk for extinction (Baura *et al.*, 1992; Wilson *et al.*, 2011). This hypothesis would also be confirmed by their rarity and restricted geographical distribution (Baura *et al.*, 1992) which could finally drive them towards an evolutionary dead-end. Miller argued that secotioid forms evolved in many genera (predominantly in the family Gomphidiaceae) as a response to adverse and stressful climatic conditions (Miller, 2003), especially moisture shortage, which might represent the principal selective factor (States and Fogel, 1999). These outcomes have been corroborated and supported by several other authors (Bruns *et al.*, 1989; Besl and Bresinsky, 1997; Hibbett, 2007; Yang, 2011; Wu *et al.*, 2014). On the other hand in the suborder Suillineae, despite it might appear much unlikely, a gasteroid form was strongly supported as the ancestral state from which both tubulate/poroid and lamellate morphologies (Suillaceae and Gomphidiaceae) could have evolved in parallel, implying an improbable although possible restoration of ballistospory via reversals of gasteromycetation and therefore a return to ballistospory from statismospory (Binder and Hibbett, 2006; Hibbett, 2007; Sánchez-García *et al.*, 2020). Recently developed evolutionary models forecast that sequestrate forms will eventually come to predominate over non-sequestrate ones in most of the clades in which they have arisen regardless the purported irreversibility of the gasteroid state, especially considering that the sequestrate condition does not preclude morphological diversification rate, rather it tends to diversify faster in gasteroid taxa than in their non-gasteroid relatives (Wilson *et al.*, 2011; Yang, 2011).

The tubulate-poroid hymenophore evolved separately at least five times in the eight lineages retrieved in the class Agaricomycetes (= Homobasidiomycetes) (Hibbett and Thorn, 2001; Kirk *et al.*, 2008). The lamellate hymenophore would have in turn arisen independently at least five times in the Boletaceae (genera *Phylloporus*, *Phylloboletellus* Singer, *Erythrophylloporus* Ming Zhang & T.H. Li and *Phylloporopsis* Angelini, A. Farid, Gelardi, M.E. Smith, Costanzo & Vizzini) and Paxillaceae (*Paxillus*) (Drehmel *et al.*, 2008; Farid *et al.*, 2018; Zhang and Li, 2018) as a deriving structure from a tubulate-poroid configuration (Pegler and Young, 1981; Neves *et al.*, 2012) and not a primeval form as previously conjectured by E.J.H. Corner (Corner, 1972a) and subsequently by R. Kühner, this latter author claiming that "...les *Paxillus* sont sans doute ceux qui rappellent le plus ce que furent les types qui ont donné naissance aux Boletaceae" (Kühner, 1977: 106). Nevertheless, the evolutionary dynamics of the hymenophore in the family Boletaceae still remain somewhat obscure (Neves *et al.*, 2012). It is proof that in the suborder Suillineae the tubulate-poroid structure would appear to derive from gills, moreover the boletinoid hymenophore (which is typical of the species formerly assigned to the genus *Boletinus* and consisting of angular and radially strongly stretched pores) would represent the intermediate evolutive step between the two extremes (Bruns and Szaro, 1992; Kretzer *et al.*, 1996).

In the family Boletaceae the convergent evolution is evident, for example, in the basidiospores ornamentation which did not take origin from a single evolutionary event but instead developed independently multiple times in several subfamilies (Binder and Hibbett, 2006; Nuhn *et al.*, 2013; Wu *et al.*, 2014). As a matter of fact, basidiospores with variously ornamented walls are

found in five subfamilies (Austroboletaceae, Boletaceae, Leccinoideae, Xerocomoideae and Zangioideae) with a predominance in the Xerocomoideae (Wu *et al.*, 2014; Sulzbacher *et al.*, 2020). The eusporial ornamentation evolved independently more than ten times in the Boletaceae from a common smooth-spored ancestor (Wu *et al.*, 2014). Specifically, in three out of the five subfamilies mentioned above smooth-walled basidiospores represented the ancestral state, the exception being the subfamily Xerocomoideae in which the ornamented spores would appear to be the ancestral state (Wu *et al.*, 2014). Such a conclusion is in contrast with Corner's theory (Corner, 1972b), who believed that ornamented spores had to be considered more primitive than smooth ones (Corner, 1972b; Pegler and Young, 1981). No information is currently available on the spore wall appearance of the common ancestor of the Zangioideae, especially in the light of the most recently described sequestrate truffle-like genus *Longistriata* Sulzbacher, Orihara, Grebenc, M.P. Martín & Baseia, which possesses longitudinally ribbed basidiospores and occupy the basal position in this subfamily (Sulzbacher *et al.*, 2020). Anyway, the results obtained by Wu *et al.* (2014) are consistent with those by Halling *et al.* (2015), who postulated that longitudinally ribbed basidiospores may alternatively represent a convergent evolution or the ancestral state of the common ancestor of *Boletellus* s.l., *Heimioporus* E. Horak and allied taxa.

Pigments and oxidation phenomena (bluing, reddening, browning and blackening) are phenotypical characters that also arose repeatedly in the Boletaceae, with the only exclusion of the subfamily Austroboletaceae where all taxa exhibit constantly unchanging sporophore tissues (Wu *et al.*, 2014). In the subfamily Zangioideae the presence of bright yellow pigments at least in some parts of the sporophores represents a unifying feature. In *Strobilomyces* the few species showing golden yellow (*S. echinatus* Beeli and *S. mirandus* Corner) or reddish brown colors (*S. brunneolepidotus* Har. Takah. & Taneyama, *S. atrosquamosus* J.Z. Ying & H. A. Wen and *S. glabellus* J.Z. Ying) are not strictly related to each other, as well as phylogenetically distant appear the species with a context directly turning blackish on exposure, consequently these morphological characters evolved several times separately in *Strobilomyces* (Han *et al.*, 2018, 2020).

As far as the TECM formation is concerned, Smith and Pfister (2009) proposed an evolutionary scenario in which, given their occurrence in the Suillineae and Boletineae and the phylogenetic distance between these two suborders, they postulated that their presence could be explained either as an ancient feature of a common ancestor of the Suillineae and Boletineae or with a convergent evolution in two separate clades of the Boletales. In any case, there have been a large number of independent losses of TECM over time in several taxa of the Boletales, remaining sporadically as a synapomorphic trait in a few genera (Smith and Pfister, 2009).

Symbiotic Partners, Mutualistic Interactions, Paleoecological Processes and Evolutionary Ecology

Ectomycorrhizal fungi are an integral part of all forest ecosystems as they mediate the interaction between plants and soil and constitute one of the most diverse and ecologically important groups of vegetation partners. It is nowadays established that more than 80% of extant plant species form symbiosis with fungi (Selosse *et al.*, 2015; Strullu-Derrien *et al.*, 2018). The number of ECM fungal species worldwide is estimated to be around 25,000, mostly belonging in the phyla Basidiomycota and Ascomycota (Rinaldi *et al.*, 2008; Tedersoo *et al.*, 2010). The acquisition of mutualistic host-symbiont associations is considered one of the key innovations promoting evolutionary diversification (Lutzoni *et al.*, 2018; Sato and Toju, 2019). As stated above, ectomycorrhizal-forming genera constitute the vast majority in the Boletales and the ECM trophic status appeared to have evolved from saprotrophism (Hibbett and Matheny, 2009; Sato and Toju, 2019; Sánchez-García *et al.*, 2020). By converse, reversal from ECM to saprotrophy is generally considered unlikely (Sánchez-García *et al.*, 2020). Recently published molecular studies suggest that ECM arose independently and asynchronously at least five times in the stem positions of the Suillineae, Sclerodermatineae s.str., Boletaceae, Paxillaceae and in the monophyletic group *Austropaxillus* Bresinsky & Jarosch/*Gymnopaxillus* E. Horak (Serpulaceae) (Hibbett and Matheny, 2009; Skrede *et al.*, 2011; Sato and Toju, 2019; Sánchez-García *et al.*, 2020). The earliest acquisition of the ECM symbiosis likely occurred in the Suillineae, followed shortly after by an evolution in the Sclerodermatineae s.str., then it more recently originated in the Boletaceae and Paxillaceae (Sato and Toju, 2019) and finally the most recent ECM evolutionary time point was observed in *Austropaxillus* (Skrede *et al.*, 2011). A single transition from a saprotrophic nutritional mode of *Serpula* to the ECM trophism of *Austropaxillus* and *Gymnopaxillus*, both being nested within *Serpula*, happened some 50–22 mya (Skrede *et al.*, 2011). As far as the Boletaceae are concerned, it is interesting to note that taxa occupying the most basal position (*Pseudoboletus*, *Buchwaldoboletus* and *Chalciporus*/*Rubinoboletus*) all have either an apparently saprotrophic or mycoparasitic trophic status, indicating that the ancestral state in the family might have been non-ectomycorrhizal (Pers. Obs.).

However, the evolution of ECM nutritional mode does not necessarily promote rapid diversification rates, particularly in the early-diverging ECM fungal lineages, as in the case of the Boletales (Sato and Toju, 2019) as well as in other groups of agaricoid fungi (Sánchez-García and Matheny, 2017; Sánchez-García *et al.*, 2020). Accordingly, the highest diversification rate in the Boletales would not be correlated to the most primeval ECM lineages, rather it appears to have occurred at a local phylogenetic scale and linked to the acquisition of mutualistic symbiosis in the more recent clade of the Boletaceae, probably contingent on the key innovation dominant pileate-stipitate morphology in this family or in combination with other biotic and abiotic factors (Sato and Toju, 2019; Sánchez-García *et al.*, 2020).

Despite the fact that some authors (Ducousso *et al.*, 2004; Alexander, 2006) speculated on a Gondwanian origin of ECM, the most ancient group of extant ECM host plants were probably the Pinaceae (Hibbett and Matheny, 2009; Tedersoo *et al.*, 2010), which were naturally distributed in Laurasia. It is not a coincidence that the genesis of Pinaceae is dated back to the Mesozoic Era, between the Lower Jurassic and Lower Cretaceous (180–130 mya), roughly the same period or slightly earlier than the origin of the

order Boletales (Malloch *et al.*, 1980; LePage, 2003; Hibbett and Matheny, 2009; Dentinger *et al.*, 2010; Lin *et al.*, 2010; García-Sandoval *et al.*, 2011; Lutzoni *et al.*, 2018), although the most primitive mycorrhizal association (endomycorrhizal) between vascular plant and fungal organisms was traced back by Honrubia (2009) to 400 mya. Based on fossil records, the ancestor of *Pinus* subgenus *Pinus* originated in the Lower Cretaceous (130–125 mya) whereas the diversification of the subgenus *Strobos* was dated to a later period, in the Paleocene, around 60 mya (Axelrod, 1986; Wu *et al.*, 2000). The most important ECM angiosperm families (Fagaceae, Betulaceae, Salicaceae, Dipterocarpaceae, Casuarinaceae, Myrtaceae, Fabaceae) originated later than Pinaceae, during the Cretaceous Period (Malloch *et al.*, 1980; Ding, 1995; Manos and Stanford, 2001; Wikström *et al.*, 2001; Thornhill *et al.*, 2015; Lutzoni *et al.*, 2018). More recent studies, however, would be inclined to date the origin of gymnosperms and angiosperms to a much more ancient time, between Carboniferous and Permian (around 300 mya) and between Late Permian (Lopingian Epoch) and Jurassic (260–180 mya), respectively (Krah *et al.*, 2018). As pointed out by Sato and Toju (2019), fossil findings indicate that Pinaceae were sporadically distributed in cool montane environments in the northern hemisphere during Jurassic and Cretaceous, conversely the major genera of Fagaceae became widespread and abundant in warm temperate and subtropical areas of the northern hemisphere from Upper Cretaceous to Late Eocene (LePage, 2003; Taggart and Cross, 2009; Tedersoo and Brundrett, 2017). Divergences in terms of distribution and habitat between Pinaceae and Fagaceae would reflect differences in fungal diversification rate and may have enabled host switches from Pinaceae to Fagaceae in the early ECM lineages. Moreover, this scenario would explain the limited diversification rate in the Suillineae and Sclerodermatineae due to a shortage of partners in the Pinaceae during Jurassic and Cretaceous, whereas the acquisition of ECM symbiosis in co-evolution with angiosperms (mainly Fagaceae) between the Upper Cretaceous and Late Eocene may have triggered a consistent and rapid, explosive evolutionary diversification of the mycobionts with a resulting acceleration of speciation in the Boletaceae (Sato and Toju, 2019; Varga *et al.*, 2019; Sánchez-García *et al.*, 2020).

Bolete genera leaning to have a more specialized trophism tend to be restricted to circumboreal geographical distribution (Pegler and Young, 1981). On a more regional scale, in eastern Mediterranean biome it seems to exist a degree of specialization between vegetational symbiotic partners and boletes, most of which appear to be associated with evergreen oaks of the ilicoid group (*Quercus alnifolia* Poech, *Q. coccifera* L.) rather than deciduous oaks (Binyamini and Avizohar-Hershenson, 1973; Loizides *et al.*, 2019).

Some of the most specialized genera are found in the Suillineae. The genus *Suillus* is associated with at least two of the four subfamilies of the Pinaceae: Pinoideae (*Pinus*), Laricoideae (*Larix*, *Pseudotsuga*) and perhaps Piceoideae (*Picea*, *Cathaya*) but not Abietoideae (*Abies*, *Cedrus*, *Keteleeria*, *Tsuga*) (Nguyen *et al.*, 2017), exceptionally it is found with Betulaceae (*Betula*), Salicaceae (*Populus*) and Fagaceae (*Quercus rubra* L.), with respect to the North American species *S. subaureus* (Peck) Snell (Smith and Thiers, 1964, 1971; Singer, 1981, 1986; Bessette *et al.*, 2000, 2016; Wu *et al.*, 2000; Nguyen *et al.*, 2017). Ecologically, the host-specificity association of *Suillus* with *Larix* appears to be primeval when compared to that with *Pinus*, *Pseudotsuga* and with broadleaved trees, these latter being thus considered as derivative (Kretzer *et al.*, 1996; Wu *et al.*, 2000). Likewise, the family Gomphidiaceae co-evolved with the Pinaceae (Miller, 2003; Watling, 2004). Mujic *et al.* (2019) investigated on the evolutionary dynamics correlated to the symbiosis *Pseudotsuga*-*Rhizopogon*, noticing that this relationship evolved just once in *Rhizopogon*. In general, from an ecological viewpoint suilloid fungi play a crucial role as primary drivers in processes of co-invasion with Pinaceae of new geographic areas outside their natural distribution range (Vellinga *et al.*, 2009; Policelli *et al.*, 2019).

The suborder Sclerodermatinae originated in mesophytic forests in ancestral association with angiosperms (rosids) and Pinaceae and only later the symbiotic linkage extended to ECM partners belonging in the Dipterocarpaceae, Ericaceae, Myrtaceae, Nothofagaceae, Sapindaceae and Fabaceae (Wilson *et al.*, 2012). It is interesting to note that the fossil genus *Palaeogaster* recently described from Birmania and preserved in amber from an australian tree source (possibly *Agathis*), dated back to the Lower-Mid Cretaceous, Upper Albion (110–97 mya), has been assigned to the Sclerodermatineae (Poinar *et al.*, 2014). It is the only fossil genus ascribable to this suborder and to the Boletales as a whole and the most ancient gasteroid genus known to date (Poinar *et al.*, 2014).

In the Boletineae, the most recent common ancestor of the sister genera *Afroboletus* and *Strobilomyces* was originally associated with members of the Cesalpinoideae, Monotoideae, Detarioideae, Phyllantaceae as the earliest symbiotic partners in Africa. Subsequently *Strobilomyces* made a host shift to the Dipterocarpaceae in tropical Asia, then switched to the Fagaceae and Pinaceae in subtropical and temperate environments in Laurasia and even more recently to the Nothofagaceae and *Eucalyptus* in the southern hemisphere (Han *et al.*, 2018). Additionally, in four lineages associated with Fagaceae/Pinaceae it has been inferred an increase of the net diversification rate respectively of four and two times higher than that of the lineages associated with the remaining symbiotic partners, testifying that host shifts provide ECM fungi ecological opportunities to enhance their distribution range, resulting in an acceleration of diversification (Sato *et al.*, 2017; Han *et al.*, 2018). In *Leccinum* the plant host *Betula* (and probably also *Populus*) represents the common ancestral symbiotic partner from which all other ECM associations derived over time (den Bakker *et al.*, 2004). It also appears that the high number of current symbiotic partners of *L. quercinum* Pilát may derive from an older monospecific association with *Populus* spp. (den Bakker *et al.*, 2004). In addition, all European members of *Leccinum* forming obligate ECM association with *Betula* spp. (*Leccinum* sect. *Scabra* A.H. Smith, Thiers & Watling) are indifferently found in temperate, boreal, subalpine and arctic habitats with the only exclusion of *L. rotundifoliae* (Singer) A.H. Smith, Thiers & Watling which is restricted to cold climates and never occurs in temperate areas (den Bakker *et al.*, 2007).

Based on the available knowledge it does not seem to be a clear evidence for a possible reversal towards a non-ECM nutritional status in the evolutionary trends of ECM lineages, although such an eventuality could not be excluded with certainty in the order Boletales (Tedersoo *et al.*, 2010). Mycoparasitism in the Boletales likely derived from an ECM nutritional mode (Binder and Hibbett, 2006; Sánchez-García *et al.*, 2020) and would have evolved at least twice independently (McLaughlin and Spatafora, 2014), in the Suillineae (Gomphidiaceae) and Boletaceae (*Pseudoboletus*) (Sánchez-García *et al.*, 2020).

Historical Biogeography, Paleo-biogeographical Dynamics and Distribution Patterns

Fungi are found in all terrestrial and marine ecosystems and represent a key component for interactions among living organisms in natural environments. Taking into consideration the kingdom Fungi in its entirety, fungal biodiversity progressively increases towards pantropical areas and the equatorial belt where average annual precipitations are more conspicuous and the degree of endemism of fungal species appears particularly pronounced with numerous taxa being confined to restricted ecological niches (Tedersoo *et al.*, 2014). However, ECM fungi appear to be more diversified in temperate and boreal ecosystems (albeit in tropical habitats the abundance of ECM species is much higher than it was generally assumed in the past, see Corrales *et al.*, 2018) and their geographic range expands towards the poles (Tedersoo *et al.*, 2014).

Fungal species belonging in the order Boletales are cosmopolitan, they occur from the equatorial belt to the arctic zones, from arid or semiarid environments to wetlands and from the sea level to the timberline or even above, up to 4000–5000 m alt. in certain ecological-climatic ecosystems (Zang, 1986, 2006), have a worldwide distribution and are found in most terrestrial biomes and in all continents with the exception of Antarctica (but they were probably also present in the latter continent during the Cretaceous in co-habitation with trees of the genus *Nothofagus*, which is not accidentally considered a sort of “living fossil”). However they are significantly more abundant in temperate habitats and most of all in the (sub)pantropical belt of the northern hemisphere with biodiversity hotspots located in North America (especially north-eastern North America), in neotropical montane cloud forests of Central America and the Caribbean and even more in eastern and south-eastern Asia, with peninsular and insular Malaysia (Borneo) being renowned as one of the world’s most important biodiversity hotspots for boletes, since this region lays at the intersection of several migration routes (Singer, 1965; Smith and Thiers, 1971; Corner, 1972b, 1993; Horak, 1983; Binder and Bresinsky, 2002b; Wu *et al.*, 2014, 2016a). By converse, members of the Boletales appear to be far less represented in the southern hemisphere, for instance in southern South America (Watling, 2001b; Palfner, 2005; Nouhra *et al.*, 2012; Truong *et al.*, 2017; Horak, 1983, pers. comm.), South Africa (Coetzee, 2011) and New Zealand (Horak, 1983) albeit decidedly more numerous in Australia (Watling, 2001b; May *et al.*, 2006).

As a demonstrative example of the biodiversity of the order Boletales in the northern hemisphere, around 500 species belonging in more than 55 genera have been reported from the sole China (Li and Song, 2000; Yang, 2005; Li and Yang, 2011; Wu *et al.*, 2016a; Pers. Obs.) with an obvious preponderance in Yunnan Province (south-western China), where the easternmost peaks of the Himalayan range and the Hengduan Mountains, owing to lighter impact of Quaternary glaciations, favorable climatic conditions of monsoon type and particularly fertile soil, presently represent one of the 35 hotspots of biodiversity worldwide, encompassing more than 17,000 vascular plants and an estimated number of fungi exceeding 100,000 species (Feng and Yang, 2018).

In sharp contrast, in most Europe and neighboring countries the biodiversity of vegetation and associated mycota is relatively low as a result of local extinctions caused by geological and climatic changes during past epochs, such as the harsh and destructive Pleistocene glaciations (Dennis, 1986; Molina and Trappe, 1994; Lodge *et al.*, 2004; Yang, 2005; Yu *et al.*, 2020) which caused the disappearance of several living organisms. Only a limited proportion of plants and fungal species survived after the regression of glaciers and it is therefore not a casualty that fungal biodiversity in Europe appears to be the poorest when compared to the greater wealth of other continents of the northern hemisphere, notwithstanding the much longer tradition of European mycological studies. Such a scenario is further corroborated by the current geographical distribution of the hypogeous genus *Alpova*, which is apparently common in Corsica, south-eastern Europe and throughout the eastern Mediterranean basin and even south into the relictual alder forests of North Africa, while it seems to be virtually absent in continental and western Europe, despite the abundant presence of its obligate symbiotic partner *Alnus* in the same area (Moreau *et al.*, 2013b). Pleistocene glaciations might explain this uneven distribution pattern with difficulties for these hypogeous fungi to follow their host trees (*A. glutinosa* (L.) Gaertn. and *A. incana* (L.) Moench) in the process of re-colonization of northern and western Europe from refuges in south-eastern Europe where they remained confined due to adverse climatic conditions (Moreau *et al.*, 2013b). Of course, further investigations in riparian areas of Carpathians, Caucasus and the Middle East might yield additional neglected *Alpova* species in the years to come (Moreau *et al.*, 2013b) and could help better understanding their biogeographic history.

In contrast to ECM species belonging in the Tricholomataceae and Cortinariaceae (especially *Cortinarius* (Pers.) Gray and *Inocybe* (Fr.) Fr.), both of which being extremely rare across the tropical belts (Buyck, 2001; Watling *in litt.*) and particularly in Africa (Bougher and Lebel, 2001), numerous Discomycetes and several genera in the orders Agaricales (especially *Amanita* and saprothrophic Tricholomataceae), Russulales and Boletales are best represented in this kind of environment, where they form ECM symbiosis mainly with members of the Fagaceae and Dipterocarpaceae in south-eastern Asia, and with Fabaceae subfamily Caesalpinoideae in subsaharan Africa and northern South America (Corner, 1972b; Singer *et al.*, 1983; Alexander and Högborg, 1986; Alexander, 1989, 2006; Newbery *et al.*, 1997; Henkel *et al.*, 2002; Lodge *et al.*, 2004; Watling and Lee, 2007). The occurrence of a multitude of boletoid genera constrained to the tropical belt may be explained with an inefficient dispersal ability or due to their failure in enduring low temperatures, resulting in a limitation or impossibility of several lineages to migrate towards temperate and subarctic ecosystems of both hemispheres (Tedersoo and Smith, 2013).

Being members of the Boletales mostly ECM and considering much unlikely, although possible, their colonization of remote geographical areas via overland long-distance dispersal, their migration might be explained with a reasonable host switch during both ancient geological times and more recent historical periods (Watling, 1981, 1988; Wolfe and Bougher, 1993; Kretzer *et al.*, 1996; Fischer *et al.*, 1997; Halling *et al.*, 2007b; Wilson *et al.*, 2012). Host shifts can no doubts be considered a successful evolutionary strategy that mediated migration routes of ECM species and their symbiotic partners between Asia and North America

across the Bering Strait (Beringian corridor). This migration is easily deductible from the disjunct geographic distribution in eastern Asia and north-eastern North America of certain species complexes, species pairs or species populations like those of *Suillus decipiens* (Peck) Kuntze/S. *spraguei* (Berk. & M.A. Curtis) Kuntze s.l., *S. americanus* (Peck) Snell/S. *sibiricus* (Singer) Singer, *S. clintonianus* (Peck) Kuntze, *Aureoboletus mirabilis* (Murrill) Halling, *Harrya chromapes* (Frost) Halling and *Sutorius eximius* (Peck) Halling (Wu *et al.*, 2000; Mueller *et al.*, 2001; Wu *et al.*, 2016a; Nguyen *et al.*, 2017; Zhang *et al.*, 2019) or otherwise from the presence in these two continents of phylogenetically closely related taxa in shared genera of the Boletaceae, such as *Bothia* Halling, T.J. Baroni & Manfr. Binder, *Retiboletus* Manfr. Binder & Bresinsky, *Pulveroboletus* and *Veloporphyrillus* L.D. Gómez & Singer (although in neither case disjunct populations belonging in the same species have been identified) (Li *et al.*, 2014a; Zeng *et al.*, 2015, 2016, 2017). Furthermore, a bi-directional exchange of plant-fungal communities between the American and Asian continents via Beringian connection would appear to be ascertained in the case of *Rhizopogon*. Dealing with the symbiosis *Pseudotsuga*-*Rhizopogon*, Mujic *et al.* (2019) placed the origin of this mutual relationship along coastal regions of the Pacific Northwest of the USA and Canada with a single event of co-migration to Asia and two independent migrations eastwards to the mountainous areas of western North America (Mujic *et al.*, 2019). This latter region constitutes at present a major center of diversity of *Rhizopogon* species, where the high speciation and diversification rate of *Rhizopogon* was probably driven by the specificity of host association with conifers (Molina and Trappe, 1994). Geographically meaningful is also the disjunct geographic distribution in the paleotropics (eastern and south-eastern Asia) and neotropics (Central and northern South America) of the genera *Erythrophylloporus* and *Rugiboletus* G. Wu & Zhu L. Yang (Vadthanarat *et al.*, 2019b; Kuo and Ortiz-Santana, 2020).

In the western hemisphere Nearctic symbiotic macromycetes (including boletes) along with their ECM plant partners moved from north-eastern North America south to Central and subsequently northern South America (as demonstrated, for example, by the strong morpho-genetic affinities between the temperate species *Tylopilus balloui* (Peck) Singer and the similar neotropical *T. leucomyelinus* (Singer & M.H. Ivory) R. Flores & Simonini and *T. oradivensis* Osmundson & Halling) across the mandatory route of the Mesoamerican isthmus (Panamanian land bridge) which connected postglacial Laurasian remnants with Gondwanan remnants between the late Miocene and the Pliocene (Halling, 1989, 1997, 2001; Wolfe and Bougher, 1993; Halling and Mueller, 2002; Halling *et al.*, 2008; Flores Arzù, 2020). Similarly to ECM boletes, some saprothrophic genera, such as the lignicolous *Gyrodontium* Patouillard, may have followed a similar migration pattern (Robledo *et al.*, 2014).

Although L.D. Gómez observed that “Es muy interesante anotar la escasa correspondencia entre las boletáceas neotropicales y las del continente africano y subcontinente indio...” (Gómez, 1997), speculations have been proposed on possible mycofloristic relationships between Latin America and central Africa, as in the case of the genus *Fistulinella* (Guzmán, 1974), yet these theories are presently premature in their essential defining lines and still awaiting for molecular confirmation, at least as far as the Boletales are concerned.

Another example of ancient geographic migrations is correlated to the ancestral population of the “Chromapes group” (including genera in the subfamily Zangioideae such as *Australopilus* Halling & Fechner, *Harrya* Halling, Nuhn & Osmundson, *Royoungia* Castellano, Trappe & Malajczuk, etc.) which likely originated in Laurasia and subsequently migrated from eastern Asia south to Australia during the glaciations of Miocene-Pliocene (which provoked the lowering of sea level and the resulting formation of intercontinental stepping-stones fragments or land bridges), initially moving into the Indo-Malayan region then across the junction known as Wallace’s Line, passing through Papua New Guinea and finally reaching the northern offshoots of Australia across the Torres Strait (Wolfe and Bougher, 1993; Halling, 2001; Halling and Mueller, 2002; Yang, 2005; Halling *et al.*, 2008; Feng and Yang, 2018). As pointed out by Wang *et al.* (2018) in relation to the ancestral area reconstruction of the lactarioid genus *Multifurca* Buyck & V. Hofst. (Russulaceae), the migration across Australasia might have also happened by island hopping. Although a bidirectional interchange between Asian and Australian continents via south-eastern Asia cannot be excluded (Halling *et al.*, 2008; Feng and Yang, 2018), as also stressed by Bougher and Lebel (2001) with respect to gasteroid and secotioid fungi associated with *Eucalyptus* and by Trappe *et al.* (2013) for the hypogeous false-truffle *Soliococcus* Trappe, Osmundson, Manfr. Binder, Castellano & Halling, a unidirectional migration from the northern hemisphere to the southern hemisphere can be virtually extended to all pileate-stipitate Australian boletes such as *Boletellus*, *Pulveroboletus* and *Strobilomyces* (Watling, 2001a-c) as well as to sequestrate hypogeous genera like *Rossbeevera* T. Lebel & Orihara owing to animal mycofagy (Orihara *et al.*, 2016b).

An alternative explanation for the current intercontinental distribution pattern might rely on a relictual presence based on a broad original occurrence of boletes in the Pangea and therefore prior to the continental drift which started between 180 mya (Varga *et al.*, 2019) and 100 mya (Heckman *et al.*, 2001; Halling *et al.*, 2008, 2015). This latter theory is strictly correlated with the ecological vicariance (Tedersoo and Smith, 2013) and had already been proposed by Trappe (1977) for hypogeous fungi. According to this scenario fungal species imprisoned into isolation on plates drifting were then likely affected by genetic drift, mutation, speciation and extinction processes that have later occurred at a regional scale in each continent independently due to locally different climatic and ecological phenomena (Horak, 1983; Wang and Qiu, 2006; Halling *et al.*, 2008), determining the noteworthy biodiversity we can currently observe (Halling *et al.*, 2012a,b, 2015).

On the other hand, in the case of *Austropaxillus* the hypothesis of transoceanic long-distance dispersal (Li *et al.*, 2009) with later vicariance events is the only plausible theory to explain the current disjunct transantarctic distribution pattern of this genus in Australasia (Papua New Guinea, Australia, Tasmania, New Caledonia, New Zealand) and South America (Chile, Argentina) (McNabb, 1969; Bresinsky *et al.*, 1999) in association with *Nothofagus* (subgenera *Nothofagus* and *Lophozonia*), since the origin of *Austropaxillus* is dated to some 23 mya, therefore posterior to the Gondwana break-up (90–80 mya) (Vergara, 2014). Moreover, it seems likely that the absence of ECM association of *Austropaxillus* with *Nothofagus* subgenera *Trisyngyne* and *Fuscospora* could be elucidated with the extinction of fungal species due to changed climatic and edaphic conditions over geological times, which

Plate 1 **a** *Boletus aereus* Bull. (MG830); **b** *Cyanoboletus pulverulentus* (Opat.) Gelardi, Vizzini & Simonini (MG708); **c** *Rubroboletus rhodoxanthus* (Kromb.) Kuan Zhao & Zhu L. Yang (MG496); **d** *Tylopilus griseipurpureus* (Corner) E. Horak (MG521); **e** *Rubinoboletus rubinus* (W.G. Smith) Pilát & Dermek (MG805); **f** *Pseudoboletus parasiticus* (Bull.) Šutara on *Scleroderma citrinum* Pers. (MG806). Photographs by M. Gelardi.

eventually resulted inadequate for their survival and reproduction (Vergara, 2014). The biogeographic connection between South American and Australasian biotopes was already postulated by Horak (1983) with respect to the co-evolution of *Austropaxillus* species with their *Nothofagus* host trees and has recently acquired further support by the close phylogenetic relationships of several fungal lineages, both in phyla Basidiomycota and Ascomycota (Truong *et al.*, 2017).

However, a significant discrepancy of fungal biodiversity appears to be obvious based on present distribution and abundance of the Boletales in each continent, for instance when comparing European with eastern Asian mycobiota. Large-scale geotectonic upsets that occurred in Paleocene and Eocene as a result of the collision of the Indian tectonic plate with the Asian continent and the ensuing formation of the Himalayan range approximately 55 mya, led to the uplift of the Qinghai-Xizang (Tibet) Plateau during the late Pliocene and Pleistocene and to the current topography of Hengduan Mountains, determining a gradual drying up with an increasing aridity of the huge surface area of western and north-western China, which became a natural barrier that virtually interrupted migration routes of fungal species between eastern Asia and Europe (Yang, 2005). Such a transformed orogenesis accompanied by dramatic landscape and climate changes determined a progressive geographic isolation which may have promoted ideal conditions for an independent evolution of species that were previously evenly distributed throughout the Eurasian continent, leading to an allopatric speciation of different populations of the same species and shaping a remarkable fungal diversification in southern and south-western China (Yang, 2005; Feng and Yang, 2018), as investigated by a number of taxonomic studies focused on *Boletus* s.str., *Zangia* Yan C. Li & Zhu L. Yang, *Phylloporus*, *Retiboletus*, *Pulveroboletus*, *Heimioporus*, *Aureoboletus*, *Strobilomyces* and many other boletoid genera (Li *et al.*, 2011b; Feng *et al.*, 2012, 2016a; Zeng *et al.*, 2013, 2016, 2017, 2018; Wu *et al.*, 2014, 2016a; Cui *et al.*, 2015; Zhang *et al.*, 2019; Han *et al.*, 2020; etc.). However, moving northward fungal differentiation tends to reduce gradually due to the presence of a natural bridge connecting Europe and Asia, which is represented by the immense Russian-Siberian forests that facilitate exchanges among different populations and therefore contribute to a lower genetic divergence (Petersen and Hughes, 2007; Pers. Obs.). Despite the Qinghai-Tibet Plateau represents a physical barrier hampering the migration of species from eastern to

Plate 2 g *Paxillus involutus* f. *eburneus* Gelardi, Segneri & Vizzini (MG670); h: *Gyroporus castaneus* (Bull.) Quél. (MG494); i: *Pisolithus* sp. (MG799); j: *Astraeus hygrometricus* (Pers.) Morgan (MG804); k: *Suillus bellinii* (Inzenga) Kuntze (MG794); l: *Chroogomphus mediterraneus* (Finschow) Vila, P é rez-de-Greg. & G. Mir (MG786). Photographs by M. Gelardi.

western areas or vice versa, the Himalayan orographic system may act by converse as a corridor for dispersal of fungal biota occurring in subalpine forests and alpine meadows like *Boletus reticuloceps* (M. Zang, M.S. Yuan & M.Q. Gong) Q.B. Wang & Y.J. Yao and *Ophiocordyceps sinensis* (Berk.) G.H. Sung, J.M. Sung, Hywel-Jones & Spatafora, which both have an omogeneous distribution throughout the mountain range (Thapa *et al.*, 2014; Feng and Yang 2018).

Based on available data species in the Boletales appear to be mostly restricted to single continents or specific geographic regions, but with some notable exceptions. The combination of a broader geographic distribution and lower fungal biodiversity in cold-temperate and boreal ecosystems have been phylogenetically highlighted for the genera *Leccinum*, *Chroogomphus* and *Suillus* (den Bakker *et al.*, 2007; Li *et al.*, 2009; Shi *et al.*, 2013), for example with respect to the Eurasian *Chroogomphus rutilus* (Schaeff.) O. K. Miller, *C. purpurascens* (Lj.N. Vassiljeva) M.M. Nazarova, *Suillus asiaticus* (Singer) Kretzer & T.D. Bruns, *S. cavipes* (Klotzsch) A.H. Smith & Thiers (Li *et al.*, 2009; Nguyen *et al.*, 2017; Scambler *et al.*, 2018) and also to *Paxillus obscurisporus* C. Hahn and *Chamonixia caespitosa* Rolland in the Paxillaceae and Boletaceae, respectively (Vellinga, *in litt.*; Orihara *et al.*, 2016a), as well as for some species in the Sclerodermataceae, Suillaceae and Boletaceae with a molecularly confirmed intercontinental holarctic distribution such as *Suillus americanus* (Peck) Snell, *S. granulatus* (L.) Roussel, *S. luteus* (L.) Roussel (this latter being the most easily encountered *Suillus* species in the world!) (Nguyen *et al.*, 2017), *Boletus edulis* Bull. (Dentinger *et al.*, 2010; Feng *et al.*, 2012; Cui *et al.*, 2015), *Imleria badia* (Fr.) Vizzini, *Leccinum scabrum* (Bull.) Gray, *L. rotundifoliae* (Singer) A.H. Smith, Thiers & Watling, *Porphyrellus porphyrosporus* Fr. & Hök E.-J. Gilbert, *Strobilomyces strobilaceus* (Scop.) Berk., *Buchwaldoboletus lignicola* (Kallemb.) Pilát, *Tylopilus felleus* (Bull.) P. Karsten and *Scleroderma venenatum* Y.Z. Zhang, C.Y. Sun & Hai J. Li (den Bakker *et al.*, 2007; Zhu *et al.*, 2014; Wu *et al.*, 2016a; Han *et al.*, 2017, 2018, 2020; Orihara and Smith, 2017; Jo *et al.*, 2019; Farid *et al.*, 2020; Zhang *et al.*, 2020). Apparently more uncommon seem to be cases of disjunct distribution in Europe and North America, exemplified by the genera *Alessioporus* and *Pulchroboletus* Gelardi, Vizzini & Simonini and by the species *Leccinum holopus* (Rostk.) Watling, *L. rufum* (Schaeff.) Kreisel, *L. variicolor* Watling, *L. versipelle* (Fries & Hök) Snell, *L. vulpinum* Watling, *Astraeus pteridis* (Shear) Zeller and *Gomphidius glutinosus* (Schaeff.) Fr. (den Bakker and Noordeloos, 2005; den Bakker *et al.*, 2007; Phosri *et al.*, 2013; Gelardi *et al.*, 2014; Farid *et al.*, 2017;

Plate 3 m *Gomphidius glutinosus* (Schaeff.) Fr. (MG613); n: *Rhizopogon roseolus* (Corda) Th. Fr. (MG782); o: *Coniophora puteana* (Schumacher) P. Karst. Frank *et al.*, 2017; Crous *et al.*, 2019; Morgado and Geml, 2020; Rossi *et al.*, 2020). It is not to be excluded, however, that future studies could reveal a circumboreal distribution by unveiling the presence of these taxa in the Asian continent, too.

A south-eastern Asian origin and subsequent diversification of several taxa in the Boletales and notably of a number of genera in the Sclerodermatineae (*Calostoma* Desvaux, *Astraeus*, *Gyroporus*, *Pisolithus*, *Scleroderma*) and Boletaceae (*Boletus* s.str.) has been suggested in recently published molecularly-based studies (Dentinger *et al.*, 2010; Feng *et al.*, 2012; Wilson *et al.*, 2012; Phosri *et al.*, 2014). The main hotspot for porcini mushrooms (*Boletus* s. str.) diversity is unquestionably south-eastern Asia and such a richness is consistent with the paleotropical origin of this genus (Dentinger *et al.*, 2010), which might have likely arisen in Australasia or the Indo-Malayan area (although a Gondwanian origin cannot be excluded) with at least two subsequent migration events towards Europe and at least four events of radiation to North and Central America across the Bering land bridge followed by vicariance/speciation at regional level between the Middle Miocene and Early Pliocene (Feng *et al.*, 2012).

An additional hypothesis namely “boreotropical migration” has been proposed by J.A. Wolfe to explain the paleotropical disjunction of living organisms in Africa and Eastern Asia (Wolfe, 1975; Morley, 2000; Zachos *et al.*, 2001) and has recently been applied to the genus *Strobilomyces* (Han *et al.*, 2018). This theory is based on the assumption of a migration of biota through the megathermal forests which extensively covered the northern hemisphere during Paleocene and Eocene, reaching their maximum range in the Eocene before to gradually contract due to global cooling between Middle Eocene and Early Oligocene and finally reducing to tropical and equatorial African and south-eastern Asian regions, thus determining the fragmentation of boreotropics and the disjunct intercontinental distribution of plants and fungi (Morley, 2000, 2003). Relying on such a scenario the African ancestral origin of *Strobilomyces* has been inferred on account of molecularly-based studies comprising a worldwide species sampling and estimated to have occurred in Early Eocene, around 50 mya (range comprised between 65 and 35 mya) (Han *et al.*, 2018). An onset migration event from Africa to south-eastern Asia took place between 50 and 43 mya across the Strait of Gibraltar and then from Europe eastward along the northern margin of the Tethys Sea (the southernmost and most tropical region of Laurasia during the Eocene), leading to the origin and separation of the *Strobilomyces confusus* Singer clade (encompassing species

characterized by echinulate-tuberculate to cristate basidiospores) and the *S. strobilaceus* (Scop.) Berk. clade (comprising species with entirely reticulate basidiospores). Subsequently, two main dispersal events happened starting from south-eastern Asia; one headed south to Australasia between the Oligocene and Miocene (36–11 mya) through the passageway generated by the collision of Sundaland and Australia at the beginning of Miocene and the other northward to East Asia during the Miocene (23–6 mya) via the collision of northern Borneo with the continental margin of southern China, followed by an additional dispersal route into Japan (which was connected to mainland Asia until the Last Glacial Maximum before being separated by the East China Sea basin). Later on, at least four independent dispersal events from East Asia to North America across the Bering Strait (whose land bridge repeatedly appeared and disappeared in the course of different geological periods owing to drastic climatic fluctuations), then to Central America (Late Miocene, 8–3 mya), and an additional most recent migration from East Asia to Europe (Late Miocene-Pliocene, 7–1.5 mya) occurred (Han *et al.*, 2018; Feng and Yang, 2018). The increasing of *Strobilomyces* species diversification rate in East Asia in the Miocene has been likely the result of a massive expansion of host plants in the northern hemisphere after a long-term retention in south-eastern Asia caused by low temperature (Han *et al.*, 2018, 2020). Most of the phylogenetic species in *Strobilomyces* appear to have a restricted geographical distribution, showing a high degree of endemism (Han *et al.*, 2018). The hypothesis of boreotropical migration and Tethys region as a corridor for dispersal and species exchanges has also been invoked to address the discontinuous distribution of floristic components in Europe and south-western China (Sun, 2001) and to justify the distribution range of the genus *Hydnum* L. which, unlikely boletes, encompasses several species shared by Europe and China (Feng *et al.*, 2016b; Feng and Yang, 2018).

In a couple of recent monographic works devoted to morphological and phylogenetic revision of the genus *Gyroporus* on a global scale, Davoodian *et al.* (2018, 2020) highlighted the existence of numerous sister relationships between East Asian and North American clades as well as phylogenetic connections between African and Australian lineages. Furthermore, they inferred a Gondwanan/southern hemisphere origin of the “castaneus clade” (comprising species related to *G. castaneus* (Bull.) Quél. s.l.) with subsequent radiations in the northern hemisphere and a Laurasian/northern hemisphere origin of the sister lineages “cyanescens clade” (comprising species related to *G. cyanescens* (Bull.) Quél. s.l.) and *G. longicystidiatus* Nagasawa & Hongo s.l. clade with a derived clade in the southern hemisphere (Davoodian *et al.*, 2018, 2020).

Another challenging topic in the biogeography of boletes that is unfortunately far from being assessed due to the lack of targeted compelling studies is the predictive distribution mapping of European and East Asian bolete species with respect to their eastern and western limits, respectively. There are some questions arising in this context; first of all, what is the easternmost natural geographic limit of apparently strictly European boletes and, likewise, what is the westernmost limit of eastern Asian boletes that are currently thought to be confined to East Asia? Secondly, there exists an intermediate geographic region anywhere in central Asia where the distribution range of certain European and eastern Asian boletes overlap? Thirdly, do the ecological requirements and abundance of these species vary when they are found in remote ecosystems far away from their fundamental center of distribution? And finally, may latitude or altitudinal gradient as well as climatic factors such as precipitations, soil moisture levels and temperature influence their overall geographic distribution extent? Whatever the case, these queries like many others related to fungal distribution patterns presently remain unaddressed and a substantial amount of work is needed to solve uncertainty surrounding specific ecological preferences and to clarify unexplained evolutionary biogeographic issues. **Plates 1–3.**

Notes on the Edibility, Toxicity and Poisonings, Therapeutic Properties, Ethnomycological Traditions, Cultivation, Consumption and Marketing

Most representatives of the order Boletales are notoriously edible, highly nutritive and constitute a relevant ethnomycological non-timber forest resource, especially for many poor communities in developing countries. On the other hand, boletes collecting represents an amusing recreational activity for foragers in developed countries. Their consumption as food by human beings dates back to the Stone Age, more precisely to the Upper Paleolithic (Magdalenian period), based on the identification via radiocarbon techniques of the spores of boletoid and agaricoid species from a tooth plaque of a 18,700 years old woman found at El Miron Cave, Cantabria, northern Spain (Power *et al.*, 2015).

It is undeniable that, among edible boletes, members of *Boletus* s. str. (commonly called “king boletes”, “ceps” or “porcini mushrooms”) can nowadays probably be considered the most iconic wild edible mushrooms worldwide and their demand is steadily growing. Porcini mushrooms are sought after, popular and largely appreciated forest-occurring fungi because of their agreeable organoleptic qualities, prized flavor and delicious taste and are commonly used as an exquisite ingredient for a large variety of processed foods. Due to the high gastronomic interest, they are extensively harvested for self-consumption and for sale purposes and currently traded at high prices on both local and global scale, generating alternative relevant economic incomes for rural communities (Hall *et al.*, 1998, 2003; Yun and Hall, 2004; Kirk *et al.*, 2008; Sitta and Floriani, 2008; Feng *et al.*, 2012; Mello, 2012; Sitta and Davoli, 2012; Peintner *et al.*, 2013; Dentinger and Suz, 2014; Wu *et al.*, 2019; Gelardi, 2020; Li *et al.*, 2021). Several other species in the Boletales are innocuous after prolonged and complete cooking, including a number of red-pored boletes such as *Suillus luridus* (Schaeffer) Murrill, *S. queletii* (Schulzer) Vizzini, Simonini & Gelardi, *Neoboletus luridiformis* (Rostkovius) Gelardi, Simonini & Vizzini (= *Boletus erythropus* Persoon s. auct. non s. orig.) (Sitta *et al.*, 2020), *N. magnificus* (W.F. Chiu) Gelardi, Simonini & Vizzini, *Rubroboletus sinicus* (W.F. Chiu) Kuan Zhao & Zhu L. Yang, *R. esculentus* Kuan Zhao, Hui M. Shao & Zhu L. Yang (Zhao and Shao, 2017), *Exsudoporus frostii* (J.L. Russell) Vizzini, Simonini & Gelardi (Bessette *et al.*, 2016) and *Xanthoconium affine* (Peck) Singer (Razanamparany *et al.*, 1986), just to name a few. likewise, in tropical Africa in order to avoid

intoxications derived from diverse cultural attitudes and cooking techniques used in different villages, the consumption of *Phlebopus* species is recommended after boiling (De Kesel *et al.*, 2017). However, caution should always be used when consuming edible red-pored boletes and, as a general rule and aside from porcini mushrooms which could also be consumed raw (even though they are somewhat difficult to digest), all other edible boletes and allied species would require pre-treatments prior to safe consumption and should by prudence be eaten only after prolonged cooking so as to make them harmless and to avoid unpleasant effects.

In the traditional Chinese folk medicine some species are considered curative or therapeutic and are used for healing various diseases, such as *Pulveroboletus ravenelii* (Berk. & M.A. Curtis) Murrill s.l. (treatment of lumbago and skelalgia, limb numbness, and improvement of the system of meridians and collaterals) (Liu, 1984; Wu *et al.*, 2013; Zeng *et al.*, 2017), whereas others appear promising in the biomedical and pharmacological fields, for example *S. placidus* (Bonorden) Singer s.l. (Liu *et al.*, 2009), *Paxillus involutus* (Batsch) Fr. s.l. (Wang *et al.*, 2012; Zmitrovich *et al.*, 2019a), *Scleroderma* spp. (Dai and Yang, 2008), *Psiloboletinus lariceti* (Singer) Singer (Denisova, 2010), *Boletus edulis*, *B. craspedius* Massee, *Fistulinella wolfeana* Singer & J. García, etc., with antioxidant properties (Tsai *et al.*, 2007; Ahmed *et al.*, 2015; Robles-García *et al.*, 2016; Dimitrijević *et al.*, 2017) and other species with potential antifungal activity against pathogenic filamentous fungi (Batool *et al.*, 2019). Certain taxa of the genera *Hortiboletus*, *Gyroporus*, *Rhizopogon* and *Tapinella* exhibit antibiotic and anticancer properties (Sasek and Musilek, 1967; Zheng *et al.*, 2006; Dai and Yang, 2008; Kim and Lee, 2009; Wu *et al.*, 2013), while antibacterial activities were observed from the acetone extracts of some species of *Buchwaldoboletus* (Madhosingh, 1966). Most recently, antioxidant, antimicrobial, anti-inflammatory and neuroprotective effects have been ascertained for the sequestrate mushroom *Octaviania asterosperma* Vittadini s.l. (Sevindik *et al.*, 2020).

A few species are inconstantly poisonous even if well-cooked (Ammirati *et al.*, 1985; Rumack and Spoerke, 1994; Benjamin, 1995; Alexopoulos *et al.*, 1996; Hall *et al.*, 2003; Mazza, 2008; Merelet *et al.*, 2012; Sarc *et al.*, 2013; Tolgor *et al.*, 2014; Chen *et al.*, 2016; Wu *et al.*, 2019; Sitta *et al.*, 2020), provoking acute gastrointestinal distress with symptoms such as nausea, violent vomiting and diarrhea and sometimes also sweating, headache, fever and hyperprocalcitonemia, such as *Rubroboletus satanas* (Lenz) Kuan Zhao & Zhu L. Yang and *Neoboletus venenatus* (Nagasawa) G. Wu & Zhu L. Yang, from which active principles responsible for intoxications (bolesatine and bolevenine, respectively) have been isolated (Kretz *et al.*, 1989, 1991; Ennamany *et al.*, 1998; Brunelli, 2007; Matsuura *et al.*, 2007), but also *Rubroboletus pulcherrimus* (Thiers & Halling) D. Arora, N. Siegel & J.L. Frank (Benjamin, 1995), *Rubroboletus pulchrotinctus* (Alessio) Kuan Zhao & Zhu L. Yang (Sitta *et al.*, 2020; Lezzi pers. comm.), *Heimioporus japonicus* (Hongo) E. Horak (Li *et al.*, 2011a; Tolgor *et al.*, 2014; Chen *et al.*, 2014, 2016; Zeng *et al.*, 2018), *Boletus huronensis* A.H. Smith & Thiers (Voitk, 2009; Bakaitis, 2012), as well as some species of *Pulveroboletus* (Sun *et al.*, 2012; Chen *et al.*, 2014; Wu *et al.*, 2014) and a certain number of species of *Scleroderma* (Stevenson and Benjamin, 1961; Arora, 1986; Bau *et al.*, 2014), although in the latter genus at least one entity endemic of Yunnan Province (south-western China), viz. *S. yunnanense* Y. Wang, is surprisingly known to be edible (best recommended when immature) and locally commercialized (Wang *et al.*, 2020; Yu *et al.*, 2020). Boletes with bitter taste (*Caloboletus*) as well as species traditionally assigned to *Boletus* sect. *Luridi* Fr. (currently belonging in several genera including *Neoboletus*, *Rubroboletus* Kuan Zhao & Zhu L. Yang, *Suillellus*, *Imperator* G. Koller *et al.*, etc.) and species of *Leccinum* and *Leccinellum* (in these two genera the stipe must be discarded being fibrous and indigestible) cause constant gastrointestinal poisoning when eaten raw or in case of incomplete cooking (Bessette *et al.*, 2000; Sitta *et al.*, 2020). Applying the guidelines provided by Sitta *et al.* (2020), species generally declared toxic such as *Tylopilus felleus* (Brunelli, 2007), *Gyroporus ammophilus* (M.L. Castro & L. Freire) M.L. Castro & L. Freire (Castro and Freire, 1995) and *Hygrophoropsis aurantiaca* (Wulfen) Maire should better be treated as occasionally or doubtfully poisonous depending on different ways of preparation. The European species *Suillellus luridus* and *Imperator torosus* (Fr. & Hök) Assiyyov *et al.* have been suspected to provoke coprinic syndrome with simultaneous intake of alcoholic beverages (Zeitlmayr, 1955; Budmiger and Kocher, 1982; Kiwitt and Laatsch, 1994; Flammer, 2008), but at least for *S. luridus* in the few reported cases in literature the intoxication might have likely derived from inappropriate preparation (insufficient cooking) or/and overconsumption and in any case attributable to a gastrointestinal context (Gry and Andersson, 2014; Sitta *in litt.*). Sporadic poisonings with gastrointestinal upset or even with allergic reactions with an immunohemolytic syndrome (Bobrowski, 1966) have been pinpointed for some thermophilic European Mediterranean species of *Suillus* associated with two-needled pine trees, namely *S. mediterraneensis* (Jacquetant & J. Blum) Redeuilh, *S. luteus* (L.) Roussel and *S. collinitus* (Fr.) Kuntze (Prager and Goos, 1984; Lavorato, 1996; Sitta, 1997; Flammer and Horak, 2003). Indeed, *Suillus* species with viscid pileus are variably laxative (the entire fruiting body, not only the pileus cuticle!) (Sitta *et al.*, 2020). A single case of intoxication with rabdomyolytic syndrome due to abundant consumption in consecutive meals of a *Leccinum* sp. mixed with *Boletus edulis* s.l. has been recently reported by Chwaluk (2013). The basidiospores of the dangerous dry rot resupinate *Serpula* spp. growing attached to indoor wooden structures of private properties were responsible of cases of asthma (Watling, 2008) and *Hydnomerulius pinastri* (Fr.) Jarosch & Besl was indicated as the probable cause of breathing problems (allergic alveolitis) (Stone *et al.*, 1989).

The collective species *Paxillus involutus* s.l. is potentially lethal, being responsible of the *Paxillus* syndrome (also known as hemolytic syndrome or allergic cytotoxic syndrome), an allergenic syndrome characterized by gastroenteritis followed by acute renal failure caused by an autoimmune hemolytic anemia reaction (formation of immunocomplexes or antibodies on red blood cells) that occurs with repeated eating of the swine fungus and may lead to the death of hypersensitive patients (Winkelmann *et al.*, 1982, 1986; Flammer, 1985; Pohle, 1995; Habtemariam, 1996; Anthowiak *et al.*, 2003; Brunelli, 2007; Assisi *et al.*, 2008). A heart attack casualty indirectly caused by the ingestion of the poisonous American bolete *Rubroboletus pulcherrimus* has been reported in literature (Benjamin, 1995). In addition, a case of fatal poisoning of a woman from an acute muscarinic syndrome occurred in Queensland (Australia) after eating mushrooms putatively belonging in the genus *Rubinoboletus* (Pauli and Foot, 2005).

Various species from the Waghi Valley in the Western Highlands of Papua New Guinea have long been considered hallucinogenic by local indigenous tribes (the so-called Nonda Mushrooms of the Kuma people), viz. *Boletus kumaeus* R. Heim, *B. flammeus* R. Heim, *B. manicus* R. Heim, *B. nigroviolaceus* R. Heim (dubitably contoxic with *Sutorius australiensis* (Bougher & Thiers) Halling & Fechner, according to Halling *et al.*, 2012a), *B. reayi* R. Heim, *Heimioporus anguiformis* (R. Heim) E. Horak and *Retiboletus nigerrimus* (R. Heim) Manfr. Binder & Bresinsky (Ross, 1936; Reay, 1959, 1960, 1965, 1977; Heim, 1963, 1965, 1966, 1972, 1973, 1978; Heim and Wasson, 1964, 1965; Watling 2001c; Toro, 2004; Treu and Adamson, 2006). Although *B. manicus* has undergone chemical testing and revealed to contain three indolic substances (Heim, 1965, 1972), scientific evidence supporting the occurrence of magic properties in these boletes has never been effectively produced, hence this phenomenon inducing an ostensible temporary madness with a range of irrational behaviors should presumably be considered a simple ceremonial staging, a sort of cultural institution, a theatrical play or a social catharsis, rather than actual effects induced under the influence of certain alleged psychotropic fungal species (Clarke, 1965; Reay, 1977; Toro, 2004; Treu and Adamson, 2006; Horak pers. comm.). Regrettably, the ethnomycological tradition of the “mushroom madness” has gradually declined and faded away among villagers over the last decades and has nowadays almost completely gone lost (Treu and Adamson, 2006). Similar psychoactive effects have been reported from consumption of a few bluing boletes in the Far East, namely *Butyriboletus roseoflavus* (Hai B. Li & Hai L. Wei) D. Arora & J.L. Frank, *Lanmaoa asiatica* G. Wu & Zhu L. Yang (these two species being considered even more favorite, renowned and appreciated in Yunnan Province than porcini mushrooms, see Wang *et al.*, 2004!) and *Neoboletus magnificus* (W.F. Chiu) Gelardi, Simonini & Vizzini (Yu *et al.*, 2020), as well as hallucinogenic would appear the Asian *Heimioporus japonicus* according to Chen *et al.* (2016) and Zeng *et al.* (2018). However, even in the aforementioned cases such a weird phenomenon equally appears implausible and should be adequately investigated for confirmation. Curiously, a reversible neurotoxicity experience after consumption of *Scleroderma cepa* Pers. has recently been reported from Germany (Haberl *et al.*, 2016).

The longest culture of consumption, preservation and trade of porcini mushrooms and related edible boletes is from Europe (especially the mycophilic Italy but also eastern European countries, as well as Finland, France, Portugal and to a lesser extent Spain) and is dated back to the ancient Greeks and Romans (Buller, 1914), although only in recent times it has achieved a much larger, international scale (Sitta *et al.*, 2007a; Sitta and Davoli, 2012; Peintner *et al.*, 2013). The practice of collecting boletes for culinary purposes in the New World is historically and intimately connected to the Italian immigrants who settled in North America at the beginning of the 20th century (Arora, 2008), starting a mycophilic tradition that was previously practically unknown. In Mexico and Central America (especially central and western Guatemala) wild edible boletes constitute an integral part of the fungal diet of several rural ethnic groups, being ethnomycological ancestral traditions consolidated since the pre-Columbian times, especially the Mayan culture (Flores Arzú, 2020; Pérez-Moreno *et al.*, 2020). Conversely, in Costa Rica and Panama consumption of mushrooms is generally low and the latter country has even been defined as mycophobic (Pérez-Moreno *et al.*, 2020). Along with other members of the family Boletaceae, porcini mushrooms are traditionally harvested during the rainy season by rural communities and offered fresh for sale in local roadside food markets as well as in urban stores in eastern and south-eastern Asia, particularly in China (especially Yunnan Province), in order to earn additional income to supplement the household economy (Wang and Liu, 2002). Indeed, members of the Boletaceae constitutes the bulk of traded wild edible mushrooms in China, with 50,000 tons of boletes gathered and sold in local and international markets (Wang *et al.*, 2020) and a total of 74 bolete species belonging in 27 genera offered for sale in the sole Yunnan Province (23% of the total mushroom species) (Pérez-Moreno *et al.*, 2020; Yu *et al.*, 2020). In addition, at least four Chinese porcini species (*B. bainiugan* Dentinger, *B. meiweiniugan* Dentinger, *B. sinoedulis* B. Feng *et al.*, *B. shiyong* Dentinger) are commonly exported sliced and dried, brined, powdered, processed or otherwise preserved to Europe due to the increasing demand of this gourmet delicacy (Wu and Lu, 2006; Sitta *et al.*, 2007b; Sitta and Floriani, 2008; Feng *et al.*, 2012; Dentinger and Suz, 2014; Feng and Yang, 2018; Gelardi, 2020; Wang *et al.*, 2020). At present, around 1000 tons of dried porcini are annually exported to Europe and the USA, for a total value of USD 19 millions (Yu *et al.*, 2020), thus generating a significant international business. Similarly, allochthonous porcini species introduced to South Africa have long been exported to Europe (Sitta *et al.*, 2007b). Among epigeous gasteroid and hypogaeus Boletales, members of *Astraeus* and *Rhizopogon* are commonly harvested and traded in local mushroom markets in Sichuan and Yunnan Provinces (Sitta *et al.*, 2007b; Wang *et al.*, 2020). Extensive cultivation trials on industrial scale of some species of *Phlebopus*, namely *P. portentosus* (Berk. and Broome) Boedijn and *P. spongiosus* Pham and Har. Takah. (the only two species of the Boletales that can be successfully cultivated under artificial conditions) with the production of basidiomes without host plants have recently started in south-western China, Thailand and Vietnam (Ji *et al.*, 2011; Kumla *et al.*, 2015; Le Thi *et al.*, 2017; Raghoonundon *et al.*, 2021), resulting in Yunnan Province in a daily yield of more than 400 kg of fresh mushrooms (Ji, 2016). *Phlebopus portentosus* is one of the most frequently consumed boletes in Asia and is considered an excellent source of protein and carbohydrates (Raghoonundon *et al.*, 2021). Although in sub-Saharan Africa there exists an ancient traditional ethnomycological knowledge related to the domestic consumption, drying and storage of non-timber forest products such as edible mushrooms with a special reference to the Sudanian woodlands in West Africa and the Zambezian miombo woodlands in Central, East and Southern Africa, boletes appear to be very rarely eaten by local indigenous people, mostly because of the soft texture and their general tendency to change color when injured (Eyi Ndong *et al.*, 2011; Härkönen *et al.*, 2015; De Kesel *et al.*, 2017; Pérez-Moreno *et al.*, 2020). As far as South America is concerned, information on traditional mushrooms consumption by endemic people is scanty and the overall knowledge of fungal diversity is still incomplete. However, *Suillus* and *Rhizopogon* species growing in exotic pine plantations in the Patagonian Andean forests of Chile and Argentina are seasonally harvested and traded locally and abroad (Sitta *et al.*, 2007a; Barroetaveña and Toledo, 2020; Pérez-Moreno *et al.*, 2020). On the other side of the Pacific Ocean, no ancient tradition of human consumption of boletes or even wild edible mushrooms as a whole appears to exist in New Zealand and the

lack of knowledge concerning the edibility of mushrooms is due to the relatively recent historical colonization of the islands. Currently, the only bolete species consumed in New Zealand are those imported accidentally from Europe alongside their exotic plant partners (Pérez-Moreno *et al.*, 2020).

Conclusions

The diversity of the Boletales in Europe and North America and to a lesser extent in East and south-eastern Asia is relatively well assessed (although new species continue to be described from Europe and North America annually, despite more than 200 years of taxonomic efforts!) with a discrete proportion of species having been sequenced in recent times, as opposed to the tropical regions of Central and northern South America as well as Australasia where a more balanced taxonomic and phylogenetic sampling is still awaiting. On the other hand, temperate South America, subsaharan Africa and northern Australia remain nowadays severely undersampled or practically ignored in this regard. Corner (1972b) and Singer (1986) claimed that bolete taxonomy can be properly understood only on the basis of a deep acquaintance of tropical species. Unfortunately, tropical habitats and the temperate belt of the southern hemisphere appear so far largely underexplored from the mycological viewpoint (Hawksworth and Rossman, 1997; Watling *et al.*, 2002; Lee, 2005; Dentinger *et al.*, 2010; Tedersoo *et al.*, 2010; Tedersoo and Smith, 2013), and a relevant fungal biodiversity might be uncovered from these remote geographic areas in the next future. It is therefore obvious that a better knowledge coupled with ongoing molecular phylogenetic investigation primarily applied to tropical mycota is presently determining and will continue to accomplish a rapid and dramatic taxonomic reassessment of historically established genera (Watling, 2008), leading to detection of unexpected mycological novelties, endorsing a better scientific investigation of understudied or neglected fungal groups, incentivating studies on their distribution, adaptation capabilities and response to climate changes, promoting awareness and conservation actions, ensuring monitoring and sustainable management of fungal inheritance and thus providing new insights into the origins, biological interactions and the fascinating dynamics of boletes biogeographic patterns.

Acknowledgments

The author is indebted to A. Vizzini (University of Turin, Turin, Italy), E. Horak (Innsbruck, Austria), G. Simonini (Reggio Emilia, Italy) for providing pertinent literature and E. Horak (Innsbruck, Austria), N. Sitta (Lizzano in Belvedere, Italy) and T. Lezzi (Acquapendente, Italy) for useful discussions. Thanks are also given to the anonymous reviewers for their constructive comments and valuable suggestions.

Functional Traits of Stipitate Basidiomycetes

Hans Halbwachs and Claus Bässler, Department of Conservation Biology, Goethe University Frankfurt, Frankfurt, Germany and Bavarian Forest National Park, Grafenau, Germany

The Rationale

Macrofungi (here: mushrooms) are highly variable in terms of basidiomes, spores, and mycelia (**Plate 1**) relating to their characteristics, i.e., to their appearance, their internal structures, or their microscopic attributes.

Centuries ago, fungal traits have led to developing a taxonomy and identification keys but not for gaining insight into fungal performance. In plant science, traits have also been used for decades to better understand plant ecology (Shipley *et al.*, 2016). Only recently, mycologists realized that appreciating trait-based functions deepens considerably the understanding of fungal behavior (e.g., Aguilar-Trigueros *et al.*, 2015; Halbwachs and Bässler, 2015; Halbwachs *et al.*, 2016).

What are functional traits? Traits are the tools for survival, reproduction, and dispersal (Violle *et al.*, 2007). In plants, e.g., a flower's color attracts insects, which may collect pollen and pollinate other blossoms. Another example is the acorn seed: its wings can carry the seed over long distances. Poisonous leaves deter herbivores (Taiz *et al.*, 2007). In fungi, analogous morphological and physiological characteristics are observed. Think of basidiome pigmentation, spore ornaments, and poisonous taxa. Fungi are generally highly variable due to environmental and/or genetic factors (pheno- and genotypic plasticity, Dawson and Jönsson, 2019), and show a plethora of traits. Their ecological functions are often not obvious. For example, why do most Boletales rely on poroid and not lamellate hymenophores, or why have some basidiomes stunted stipites? In any case, most traits come at costs. Especially pigments and other secondary metabolites need considerable energy input for synthesis, probably leading to trade-offs. Trade-offs are imminent because the energy budget of organisms is inevitably limited (Mayhew, 2006).

A word of warning: The general notion that everything in nature has a function is still under scientific debate. One should be aware that nature is the result of evolution, which is, in general, not a directed process but the result of try and error. As Jacob (1977) so aptly coined it: "evolution is a tinkerer".

Functional fungal traits refer to their morphology, physiology, and behavior of mycelia, basidiomes, and spores. The following sections provide insight into the connection of such traits with vital fungal functions. Note that many interpretations are based on plausibility and not on evidence.

The Mycelium

Morphological Traits

Although basidiomycete mycelia are abundant, e.g., in forest soils (**Fig. 1**), our understanding of their distribution, dynamics, and functioning is limited.

The contribution of individuals, i.e., physically and (or) physiologically delimited mycelia (genets), to nutrient translocation and cycling in forest soils is across species still largely unknown (Cairney, 2005). It is self-evident that the extent (coverage) of mycelia in the substrate echoes its ability to extract nutrients. However, there is more to mycelial morphology, as the following sections show.

Plate 1 Spores, mycelia, and various mushrooms. Spores Linas Kudzma CC BY-SA 3.0, courtesy Gernot Friebe, mycelia Bob Blaylock, Tobi Kellner CC BY-SA 3.0, mushrooms courtesy of Shawn Fischer.

Fig. 1 Mycelium of *Agaricus bisporus* with basidiome embryos (primordia), bar 1 mm. Pradejoniensis CC BY-SA 3.0.

Mycelial coverage, mycelial biomass

The ability to form extensive mycelia, for instance in *Armillaria* (Rizzo *et al.*, 1995), is coupled with competitive (Brasier, 1999) and reproductive fitness (Dawson *et al.*, 2018). The size of species-specific mycelia may limit the size of basidiomes.

Vertical distribution

Generally, mycelia of saprotrophic fungi occur in the higher and younger organic layers, while ectomycorrhizal taxa prefer lower strata where humus accumulates and make nitrogen available for host plants (Lindahl *et al.*, 2007; Scattolin *et al.*, 2008). This spatial distribution reflects the decomposer qualities of the two guilds.

Hyphal cords and rhizomorphs

Cords and rhizomorphs are employed by some species when nutritious patches occur at a distance (Cl  men  on *et al.*, 2012), thus having the edge over less competitive species.

Ectomycorrhizal mantles

Ectomycorrhizal Agaricomycetes colonize host plant roots by forming hyphal mantles, which act as interfaces for exchanging nutrients and other beneficial compounds (Smith and Read, 2008). There exists a host of different mantle types in terms of morphology, texture, structure, and pigmentation (Agerer, 1987–2002). The ecological implications of the mantle types largely remain in the dark. Commonly, the mantles store nutrients for the development of sporocarps (Taylor and Alexander, 2005).

Extramatrical mycelia, exploration types

Ectomycorrhizal fungi show typical extramatrical mycelia. They can be classified into long-, medium- and short-distance, contact, and pick-a-back, which may represent trade-offs between mycelial coverage and decomposition abilities (Agerer, 2001) (see below Section “Guild-Specific Trait Syndromes”).

Common mycorrhizal networks (CMN)

Ectomycorrhizal mushrooms form hyphal networks that connect them among themselves and host trees (“wood-wide-web”) and distribute water, nutrients and signaling compounds (Simard *et al.*, 2012), even if the latter are mixed stands (Simard *et al.*, 2015). In this way, CMN contribute to stabilizing forest ecosystem resilience to disturbance (Rhodes, 2017; Gilbert and Johnson, 2017).

Hyphal wall thickness

Thick-walled mycelial hyphae store nutrients (carbohydrates) (Cl  men  on *et al.*, 2012), which may be interpreted as a way to “sit out” unfavorable conditions (e.g., dry spells, extreme temperatures), thus improving stress tolerance. A number of species develop mycelia with relatively thin hyphal walls and low chitin content, e.g., waxcaps, which may increase the efficiency of nutrient uptake (Halbwachs *et al.*, 2013).

Clamp connections

Clamp connections in mycelial hyphae are the regular case in Agaricomycetes. They signify the development of a dikaryotic mycelium produced by meiosis leading to diploidy. It gives these fungi the advantage of recombination, i.e., high genetic adaptability (Moore *et al.*, 2011). It should be noted that in clamp-less, aseptate hyphae, i.e., coenocytic hyphae, the occurrence of multiple nuclei may be an alternative way of keeping up genetic adaptability (Moore *et al.*, 2011).

Mitospores

These basically asexual spores such as arthroconidia and chlamydospores serve as a back-up system when adverse conditions do not permit fructification. Mitospores occur, e.g., in *Asterophora*, *Pleurotus*, *Lentinellus*, *Rhodotus*, and *Volvariella* and can be dispersed by animals and perhaps wind (Cl  men  on *et al.*, 2012).

Fig. 2 *Polyporus tuberaster* (Jacq.) Fr. with its typical sclerotium. Alan Rockefeller CC BY-SA 3.0.

Mycelial cysts and cystidia

In, e.g., *Coprinellus*, *Pholiota*, *Stropharia*, and *Pleurotus* occur allocysts and thrombocysts. *Auriscalpium*, *Russula*, *Lentinellus*, and *Stropharia*, for example, may produce cystidia (Gleo- or acanthocytes) (Cl  men  on *et al.*, 2012). The function of these structures is unclear but could be excretory organs producing substances that alleviate biotic and abiotic stress, e.g., latex-producing gleocystis in *Russula* (see below Table x, Section "Basidiome Physiology").

Sclerotia and pseudosclerotia

Like thick hyphal walls, sclerotia and pseudosclerotia store carbohydrates or portions of the substrate to outlast adverse conditions (Cl  men  on *et al.*, 2012) (Fig. 2). Pseudosclerotia are mostly tough hyphal aggregates, which may become large as a football (Macfarlane *et al.*, 1978).

Physiological Traits

Mycelia do not only access and transport nutrients and water but are, at the same time, chemical factories. They produce an abundance of compounds, mainly enzymes and secondary metabolites, such as extrahyphal enzymes to cleave, e.g., cellulose, hormones, toxins, thermal protectors, and fungivore deterrents.

Many mushrooms have mycelia resistant to microbial and predator attacks (e.g., *Collembola*). Melanins (dark pigment) are well known for their protective qualities (Bell and Wheeler, 1986) (see Box 1). For instance, Bjorbaekmo *et al.* (2010) reported that many fungi associated with *Dryas*, an alpine/arctic shrub, show melanized mycelia. Moreover, some volatile organic compounds (VOC) and other secondary metabolites show repelling qualities (Moore *et al.*, 2014; Spiteller, 2015). Especially melanins are costly to synthesize, which probably leads to a trade-off with, e.g., mycelial growth (Koide *et al.*, 2014; Siletti *et al.*, 2017). Conversely, Crowther *et al.* (2014) found that strong competitors cannot tolerate desiccation well. On the other hand, some species may not only tolerate a specific stressor such as heat but a combination of stressors (Treseder and Lennon, 2015) by employing heat shock proteins and antifreeze compounds (mainly sugars and some lipids). Apart from house-keeping enzymes and hormones, compounds that protect against biotic and abiotic hazards are crucial for survival and fruiting competence.

If not growing in patches not yet colonized by other fungi, many mycelial hyphae show the ability to fend off hyphae of other fungi (competitive exclusion or growth deadlock: Cairney, 2005). Ectomycorrhizal fungi often outcompete saprotrophic taxa ("Gadgil effect", Cairney, 2005; Gadgil and Gadgil, 1975), though this effect varies with soil horizons and season (Per  oh *et al.*, 2018). The antagonistic mycelial interaction between different taxa is often controlled by excreting secondary metabolites that suppress the growth of foreign hyphae (K  es *et al.*, 2018) or even kill them (Silar, 2012). Not only chemical but also physical defense mechanisms can be observed, e.g., blocking foreign mycelia by hyphal proliferation at the point of contact (Widden, 1997). Ectomycorrhizal taxa and lichens are renowned for their ability to dissolve mineral matter, among others, to enable the uptake of mineral phosphorus, which is not readily soluble (Gadd, 2017).

Box 1 Functional properties of fungal melanins

- (1) Structural enforcement (cell walls) against osmotic and turgor forces
- (2) Desiccation protection
- (3) Thermal stress protection
- (4) Protection against ionising radiation (UV, γ -radiation etc.)
- (5) Salt and pH stress protection
- (6) Mopping up heavy toxic metals
- (7) Antioxidant
- (8) Protection against lytic enzymes
- (9) Fending off microbial attacks
- (10) Enhancing virulence of plant pathogens
- (11) Converting radioactive and other radiation to energy for metabolic processes

Melanized hyphae

The degree of hydrophobicity of, e.g., ectomycorrhizal mycelia, seems connected to substrate water content (Smits *et al.*, 2003) and nutrient distribution (Unestam and Sun, 1995). Hydrophilic mycelia are more water stress-tolerant, hydrophobic mycelial strands transport nutrients from more distant patches. Hydrophobicity may dramatically increase with age (Smits *et al.*, 2003). The ecological implications of this phenomenon are unknown.

Behavior

Little is known about behavioral traits in mycelia. Their traits seem primarily relate to autecological functions:

Aerotropism

Hyphae grow away from the colony center towards higher oxygen concentrations (Ugalde, 2006) to exploit new resources.

Autotropism

Hyphae show positive autotropism by growing hyphal branches (Ugalde, 2006) to possibly form a network, which may optimize metabolite distribution in the mycelium. Negative autotropism prevents hyphae from growing back to older parts of the mycelium (Ugalde, 2006), where resources have become depleted.

Chemotropism

Fulton (1906) found that hyphae of, e.g., *Coprinus cinereus* grow towards higher nutrient concentrations, while Gooday (1975) found little evidence that resource gradients affect hyphal growth.

Phototropism

Reinert (1959) reported negative phototropism, which is perfectly plausible regarding substrate exploitation and desiccation prevention.

Thigmotropism

Contact stimuli direct hyphae away from obstacles towards crevices, cavities, and pores (Gow, 1994; Perera *et al.*, 1997).

Mycelial persistence

Combative taxa like *Armillaria*, possess mycelia that live several years up to several hundred years (Burnett, 2003). Although it can be expected that small and ephemeral Agaricomycetes, which colonize $\pm$ fresh litter, develop short-lived mycelia, little is known about mycelial longevity (Burnett, 2003).

Host specificity

Most lignicolous saprotrophic mushrooms are promiscuous, i.e., occur on deciduous and coniferous wood but may have preferences (Krah *et al.*, 2018). Some only colonize deciduous, others only coniferous substrates, palm trees, ferns, or grasses. Only a few species are associated with specific host genera, such as *Mucidula mucida* with *Fagus* (Knudsen and Vesterholt, 2012).

Ectomycorrhizal taxa are more often host-specific, and some are even Genus-specific, e.g., *Suillus grevillei* with *Larix*, *Lactarius torminosus* with *Betula* and *Cortinarius archeri* with *Eucalyptus* (Molina *et al.*, 1992).

It can be expected that such traits form a functional consortium (syndrome) to optimize the investment of resources/energy.

The Basidiome

Basidiomes of Agaricomycetes (mushrooms) carry the machinery for sexual reproduction and dispersal. Reproductive and dispersal fitness depends on morphological and physiological adaptations of basidiomes to abiotic and biotic environmental conditions and the resulting ecological niches (Schoener, 2009; Halbwachs *et al.*, 2016). These adaptations become manifest in functional traits or their combinations (Crowther *et al.*, 2014; Shipley *et al.*, 2016; Perez-Harguindeguy *et al.*, 2013).

Basidiome Size and Number

The size range of mushrooms is overwhelming: some species develop cap diameters smaller than 1 mm, others attain up to 1 m (Plate 2). Larger basidiomes survive longer and produce more spores than smaller ones (Moore *et al.*, 2008). Species with (many) small basidiomes tend to fructify and perish faster and are thus adapted to rapidly changing and potentially perilous conditions (Bässler *et al.*, 2016).

Mycelium of a given size may either produce few large fruit bodies or numerous small fruit bodies. Indications of such a trade-off have been found by Bässler *et al.* (2015). Small fruit bodies have the advantage that a fungus can quickly utilize ephemeral resources for dispersal and reproduction. Larger fruit bodies can sustain longer periods and maximize their spore production, thus having a competitive advantage.

Basidiome Architecture

Although the standard blueprint of mushrooms is based on stipe, cap, and hymenophore (spore-producing tissue), these fungi show differing shapes (Fig. 3) (Halbwachs *et al.*, 2016). The basic characteristics of fruit bodies serve multiple purposes, mainly relating to structural stability, protection against hazards, and dispersal optimization.

Apart from implications for dispersal and reproduction, basidiome shapes predominantly have adaptive qualities relating to abiotic and biotic threats (Table 1).

Fig. 3 Main basidiome types. From left to right: convex, plane with umbo, conical/bell-shaped, funnel-shaped.

Table 1 Main features of basidiome architecture and their putative ecological implications. Examples are depicted in [Plate 3](#)

Architectural features	Examples	Interpretation
Slim cap	<i>Coprinus comatus</i>	Keeps humidity in the sporophore, minimal investment in trama
Tall habit	<i>Amanita bisporigera</i> , <i>A. crocea</i>	The hymenophore is raised above the still air layer next to the ground so that air movement can carry away the spores
Stocky habit	<i>Lactarius turpis</i>	Traps humidity, spore dispersal predominantly by invertebrates, withstands harsh winds
Cap convex to flat	<i>Boletus aereus</i>	When fleshy, a good water and nutrient reservoir for spore generation and release, barrier to the sporophore, insulation against excessive temperatures, optimal space for the sporophore, turbulent air reaches sporophore without obstruction
Cap funnel-shaped (infundibuliform)	<i>Trogia</i> sp.	Unobstructed access to vectors, minimal investment in trama. Whether the cap depression serves as water-collecting structure, is unknown
Cap bell-shaped, conical	<i>Psilocybe mexicana</i>	Cap often loosely attached to stipe and thus keeps lamellae in a vertical position regardless of stipe angle ("gravitational suspension"), minimal investment in trama
Cespitose (clustered) growth	<i>Hypholoma fasciculare</i>	Overcomes spatial constraints: one large fruit body would be squeezed at the tree trunk, traps humidity
Pellis scaly* (squamulose), wooly (tomentose), bristly (strigose) etc.	<i>Sarcodon imbricatus</i> , <i>Lactarius pubescens</i>	Insulate against heat, bar UV radiation, reduce desiccation, may deter fungivores, may be water-repellent
Glutinous coating*	<i>Gliophorus psittacina</i>	Probably protects against desiccation and/or bars fungivores
Hydrophobic pellis	<i>Boletus aereus</i>	Hydrophobic cap coating prevents excessive water and probably pathogens penetrating deeper tissue strata (Lugones et al., 1996)
Veils, cortinas, volvas, and rings*	<i>Amanita jacksonii</i>	These structures are remnants of the universal veil, which encases the emerging fruit body. They serve as protection against fungivores and desiccation, especially the young fruit body
Cap umbo	<i>Amanita crocea</i>	Probably for bracing the junction between stipe and cap and for keeping the cap horizontally
Tapered stipe	<i>Amanita bisporigera</i> , <i>Gomphidia roseus</i>	Upwards: suggestive of a trade-off between biomass economy, fruit body stability and geotropic orientation of the hymenophore Downwards: stability ensured by surrounding substrate
Stipes with transversal density gradient	<i>Macrolepiota fuliginosa</i>	Hollow, cavernous or loosely stuffed stipes possess a higher tensile strength than full stipes, which improves the stability of tall mushrooms
Eccentric stipe	<i>Pleurotus ostreatus</i>	Prevents caps to become squeezed at tree trunks (entry point for microorganisms!)
Bulbous stipe	<i>Amanita bisporigera</i>	Anchor to substrate

*Defensive structures.

Note: Halbwachs, H., Simmel, J., Bässler, C., 2016. Tales and mysteries of fungal fruiting: How morphological and physiological traits affect a pileate lifestyle. *Fungal Biology Reviews* 30, 36–61.

Micro- and macrobial pests largely constrain the longevity of mushrooms. Consequently, fungi are equipped with defensive structures. Numerous morphological features physically deter fungivores, particularly when fungi are still young. At the same time, such structures may give protection against abiotic hazards. None of these traits can prevent damage; they merely extend the lifetime of fruit bodies and thus the sporulation period(s). It should be noted that basidiome size is correlated with longevity ([Moore et al., 2008](#)). Some structural basidiome traits seem not to serve a function, for example, undulate or crenate cap margins, which deserves further research (see B and I in [Plate 3](#)).

Hymenophores

There are basically four hymenophore architectures (**Plate 4**):

Each architecture exhibits a typical hymenial surface area per area unit of the cap underside. Gills provide the most efficacious architecture, followed by tubes, teeth, and smooth hymenophores (Pöder, 1983) (**Fig. 4**).

Lineages with less efficacious hymenophores must either have a compensatory feature or have other advantages. Ways for compensating hymenial area loss could include larger fruit bodies or the production of multiple fruit bodies, thus increasing the size of the hymenophore-bearing cap. Another way could be a higher spore packing density by producing more elongate spores while maintaining their volume.

The role of cystidia in many taxa is multifaceted. They act as secretory organs that are possibly involved in hymenial water regulation, as stabilizers that maintain gill patterns during development (Moore *et al.*, 1998), as spacers to keep basidia apart (Largent *et al.*, 1978), and as fungivore deterrents (Nakamori and Suzuki, 2007).

Basidiome Physiology

Like mycelia, fruit bodies make use of a wide array of enzymes and secondary metabolites, especially for fending off fungivores or hazardous microorganisms (Halbwachs *et al.*, 2016). Guild-specific characteristics are treated below in Section “Guild-Specific Trait

Plate 4 The four hymenophore types: A lamellate (gills) (*Megacollybia platyphylla*), B poroid (tubes, pores) (*Leccinum manzanitae*), C hydroid (teeth) (*Hydnellum aurantiacum*), D smooth (*Craterellus cornucopioides*). Syndromes". In the following, important secondary metabolites found in mushrooms and their putative ecological function are accounted for.

Pigments

Most pigments can be attributed to functions such as antibiosis (e.g., blueing in many boletes when bruised) (Spiteller, 2015), bacterial defense (e.g., yellow mycenaaurin in *Mycena aurantiomarginata*) (Jaeger and Spiteller, 2010), antioxidant (e.g., betalains in some *Hygrocybe*) (Belhadj Slimen *et al.*, 2017; Bresinsky and Kronawitter, 1986), toxicity (e.g., blue-violet L-Dopa-based neurotransmitter in *Cortinarius*) (Gill, 2003; Misu and Goshima, 2006) and thermal regulation (e.g., melanins in *Boletus aureus*, see Krah *et al.*, 2019). For further details on pigments, refer to Gill and Steglich (1987) and Gill (2003). See examples in Plate 5.

Yellow seems to particularly attract flies and beetles (Menzel and Shmida, 1993; Prokopy and Owens, 1983). In horticulture, yellow sticky traps are widely applied to minimize insect infestations. It has been speculated that bright colors, especially hues from yellow to red, would serve as a warning cue to predators (aposematism) (Komárek, 2003). As yet, such an interaction could not be proved.

Volatile organic compounds (VOCs)

1-octen-3-ol deters slugs, e.g., in *Clitopilus prunulus* (Wood *et al.*, 2001) but also lures insect vectors (Combet *et al.*, 2006), an impressive case of trait multi-functionality and chemical economy in fungi. Also, other VOCs may be attractants for vectors (Boddy and Jones, 2008), e.g., the carrion smell of Phallales, which attracts flies. Some mushrooms virtually produce odor bouquets (Kües *et al.*, 2018). There are indications that toxic fungi develop warning odors (Sherratt *et al.*, 2005).

Taste compounds

Bitter or pungent compounds may deter some mammalian fungivores (Spiteller, 2015); other, e.g., sugary compounds may attract vectors (Dawson *et al.*, 2018).

Toxins

Many mushrooms are toxic for fungivores (Spiteller, 2008), albeit selectively. For instance, *Hypholoma fasciculare*, which is toxic to humans, is readily consumed by roe deer (authors' observation). Hallucinogenic substances, like psilocybin, often lead to an aversion to a fungus (Camazine, 1983) or may cause an intoxicated vector to erratically move and thereby disperse spores more widely (Boyce *et al.*, 2019).

Latex

Some taxa (mainly *Mycena*, *Lactarius*, *Lactifluus*) produce, upon exposure to oxygen, milk that then turns to latex, which may act as wound closure to prevent microorganisms from entering the trama.

Texture

Another physiological aspect of basidiomes is texture. Basidiomes of most Agaricomycetes are monomitic (consisting exclusively of generative hyphae). They are fairly rigid when young due to hydraulic pressure (turgor) (Beecher *et al.*, 2001). Senescence sets in when trama loses water and, in consequence, becomes soft. Di- and trimitic fruit bodies (also possessing skeletal and/or binding hyphae) are tougher than monomitic ones, for example, *Megacollybia*, and *Trogia*, a trait that leads to extended longevity (Dawson *et al.*, 2018). The frequently observed considerable force exerted by mushrooms to break through compacted soil is not connected to a tough texture. This force is purely hydraulic and amounts to around 0.5 Newton/mm² (Halbwachs and Bässler, 2012), which means that e.g., an emerging basidiome of *Agaricus bisporus* may lift a weight of several kilograms, a quality that may be instrumental in skeletal and root-rich soils.

Luminescence

Bioluminescence in fruit bodies (Fig. 5) possibly attracts arthropod vectors (Sivinski, 1981; Oliveira *et al.*, 2015) since their green sensitivity matches the emission peak of luminescent fungi (Shimoda and Honda, 2013; Desjardin *et al.*, 2008) in the *Omphalotus*, *Armillaria* and *mycenoi5* lineages (Desjardin *et al.*, 2008).

Basidiome Behavior

Basidiomes show some physical reactions to environmental cues:

Gravitropism (geotropism)

Mushrooms need to orient their hymenophore in a way that spores can be discharged without being obstructed. In most taxa, the stipe bends to maintain a horizontal position of the cap; some species can adjust their hymenophores (Moore *et al.*, 1996).

Phototropism

Phototropism may take over from gravitropism to enable the basidiome to grow out from, e.g. a crevice into the open. Then, geotropism takes over again to bring the cap into a horizontal position (Halbwachs *et al.*, 2016). For many taxa, blue light is required for basidiome initiation (Corrochano and Galland, 2006).

Fig. 5 *Mycena chlorophos*, a sub-tropical luminescent saprobic mushroom. Steve Axford CC BY-SA 3.0.

Thigmotropism

Negative thigmotropism, combined with gravitropism, leads to an avoidance of obstacles, such as dense turf, which may result in contorted stipes (Fig. 6(A)) (Halbwachs *et al.*, 2016).

Dwarfing

Dwarfing may occur in dry years (Halbwachs *et al.*, 2016) or due to low temperatures (Halbwachs and Simmel, 2018). See also Section “Trait Variability” in this chapter.

Fairy rings

Fairy rings, i.e., the simultaneous development of multiple fruit bodies along a circle or arc, predominantly occur in grassland under dry conditions (Griffith and Roderick, 2008) (Fig. 6(B)). They can attain diameters of several hundred meters and an age of several hundred years (Shantz and Piemeisel, 1917). Fairy rings may be visible signs of competitive competence without any specific function.

Phenology

Fructification timing, though largely determined by environmental factors such as precipitation and temperature (Halbwachs *et al.*, 2016), has a genetically controlled component (Selosse *et al.*, 2001). There are indications that many Agaricomycetes avoid fructification during the peak season of fungivorous insects (Halbwachs, 2019) (see also below Section “Guild-Specific Trait Syndromes”).

The Spore

Fungal spores combine two capacities critical for fungi, namely reproduction and dispersal. The basidiomycete mushrooms reproduce sexually by merging germ tubes that emerge from different spores. The morphological diversity among all mushroom clades is legendary (Fig. 7). Be it size, shape, ornamentation, pigmentation, or other features, most of their functions are still subject to speculation, albeit with some plausibility.

Spores Size

In mushrooms, mean spore size (length) ranges between ca. 2.5 μm (e.g., *Cystolepiota luteohemisphaerica*) and 20.5 μm (*Hymenopellis megalospora*). Even more impressive are the volume differences of these species. The latter is ca 300 times more voluminous. For a given hymenial surface area and a given spore shape, the investment in biomass of large spores is higher than for small spores. This may seem counterintuitive. But as a matter of fact, spore volume follows a cubic function of the diameter (Halbwachs *et al.*, 2018).

Fig. 6 A: waxcaps with contorted stipes caused by thigmotropism, B: fairy ring of *Chlorophyllum* sp.

Fig. 7 Various basidiospores. Courtesy of Henning Knudsen.

The ecological implications of spore size are summarized as follows.

Discharge

The larger a spore, the further it is discharged because the spore length determines the size of Buller's drop (Stolze–Rybczynski, 2009). The larger Buller's drop, the more forceful it hits the spore's adaxial area and is severed from the basidium (Clémenton *et al.*, 2012). This may be the reason that in poroid mushrooms, spores become larger with tube diameter (Stolze–Rybczynski *et al.*, 2009).

Wind dispersal

Small spores are further dispersed by wind than large spores (Norros *et al.*, 2014). This due to the lower settling speed of small spores (Edmonds, 1979).

Impaction

Large spores have a higher impact on substrates facilitating establishment while small spores more easily circumvent obstacles during their flight (ruderal mushrooms) (Halbwachs and Bässler, 2015).

Desiccation resistance

There are indications that spore size can be related to fruiting phenology and humidity. Kauserud *et al.* (2010) found that basidiomycete assemblages have, on average larger spores under dry conditions than in humid regimes and hypothesized that it is a strategy to store water for germination.

Dormancy

Large spores contain carbon nutrients that prolong survival (Hawker and Madelin, 1976). See the next section for a size-shape syndrome in ectomycorrhizal mushrooms.

Germinability

Small spores readily germinate, which is advantageous, e.g., at higher latitudes where the window of opportunity is narrow (Cline and Zak, 2014).

Spore Shape

Most mushroom spores are fusiform to oval (oblong, ellipsoid) or globose, some ovoid, and some irregularly shaped (e.g., bean-shaped (phaseoliform), sausage-shaped (allantoid) and more), see Largent *et al.* (1978). Putative functions of such spore shapes are compiled in the sections below.

Discharge

Oblong spores discharge further because the spore length determines the size of Buller's drop (Stolze–Rybczynski, 2009). Perhaps, oblong spores produce elongate adaxial drops, thus increasing the discharge momentum by higher leverage.

Wind dispersal

Studies are showing that spore shape does not affect dispersal distance (Crandall, 2016; Hussein *et al.*, 2013). In contrast, e.g., Peay *et al.* (2012) and Tulloss (2005) reported that elliptical spores are carried further by wind than round ones. This is corroborated by studies that showed that elliptical spores occur more often in open forests (chaparral) (Botnen *et al.*, 2019) and nutrient-deprived settings (Halbwachs *et al.*, 2017). The contradictory findings need to be disentangled.

Impaction, substrate attachment

Allantoid spores may be well suited for clinging to woody surfaces; litter dwellers mostly have spherical spores (Calhim *et al.*, 2018).

Dormancy

Globose spores exhibit the smallest surface area compared to oblong ones with the same volume. In this way, a minimum surface area is exposed to microbial attacks and threatened by desiccation (Carlile *et al.*, 2001), which may be important for the ectomycorrhizal guild where spores need considerable time to get in contact with host rootlets. This correlates to spore size, which is phylogenetically rooted (Bässler *et al.*, 2015).

Production (numbers)

Evidently, more elongate spores can be produced per hymenial surface area unit than globose ones with the same volume. However, elongate spores are more costly to produce than globose ones having the same volume in the sense that internal spore structures are needed to prevent distortion (Kauserud *et al.*, 2008).

The ecological relevance of most spore shape variants has still to be elucidated. It could well be that, e.g., a bean-like shape bears no ecological meaning at all but is a mutational oddity that does not entail any disadvantage or advantage for a fungus.

The Spore Wall

Mushroom spores are encased in a multi-layered, protective membrane. Smooth and unpigmented (hyaline) ones have two layers; all other types that show ornamentation and/or pigmentation have five layers (Clémenton *et al.*, 2012). Spore wall traits are related to numerous functions that are connected to reproductive and dispersal fitness.

Ornamentation

Smooth spores seem to be dispersed predominantly by wind (Dawson *et al.*, 2018), and are typical for terrestrial saprotrophic mushrooms (Calhim *et al.*, 2018). Ornamented spore walls appear to be instrumental for dispersal by vectors, especially in the ectomycorrhizal guild (Halbwachs *et al.*, 2015; Vašutová *et al.*, 2019) (Plate 6-A), and for better clinging to woody substrates (Calhim *et al.*, 2018). Unexpectedly, ornamentation does not significantly contribute to air dispersal efficacy (Roper *et al.*, 2008), at least in ascomycetes.

Pigmentation

About 50% of all mushrooms produce melanized (dark) spores, at least in Scandinavian countries (Halbwachs *et al.*, 2015) (Plate 6-B) for protection (see Box 1). Fungal melanins are costly to produce (Rohlf and Churchill, 2011) and require thick spore walls (Garnica *et al.*, 2007). To a lesser extent, pigments other than melanins also have protective qualities, e.g., carotenoids (Ruiz-Herrera, 2012; Gooday, 1981).

Appendages

Winged (calyptrate) spores as they occur in *Coprinopsis* (Plate 6-C) and *Galerina* have an extended outer wall layer (myxosporium). One may speculate that this trait slows down sedimentation, which would result in long-distance dispersal by wind, though Jones (2006) surmised that appendages (in ascomycetes) serve attachment to substrates rather than dispersal efficacy.

Hydrophobicity

Hydrophobic spores (mostly ornamented > Lotus effect) and are electrostatically attracted by water drops (Davies, 1961) and cuticles of arthropods (Ruddick and Williams, 1972). Therefore, hydrophobic spores can be transported by mist and insects. Rainfall washes out any spore larger than 2 µm (Henis *et al.*, 1987).

Germ pore

Germ pores have presumably evolved to allow thick-walled spores to quickly germinate, especially in coprophilous taxa (Garnica *et al.*, 2007) (Plate 6-D). Except for a few species (e.g., in *Inocybe*), spores of ectomycorrhizal taxa do not show germ pores (Halbwachs *et al.*, 2015), which may relate to prolonged dormancy.

Wall thickness

Thick spore walls are instrumental for taxa, which use aggressive substrates, e.g., dung dwellers (Garnica *et al.*, 2007) (Plate 6-D). Moreover, thick-walled spores may show prolonged dormancy (memnospores), while thin-walled xenospores are better suited for dispersal and quick germination (Dix and Webster, 1995). Note that there seems to be a correlation between spore wall thickness and spore size (Halbwachs and Bässler, 2020).

Plage (suprahilar depression)

The plage is a hydrophilic spot (Fig. 8) adjacent to the apiculum where Buller's drop hits the supra-apicular drop when the spore is discharged (Clémenton *et al.*, 2012). See also Sections "Spore Size" > "Discharge".

Guild-Specific Trait Syndromes

In the saprobic and ectomycorrhizal guilds, some specific morphological and behavioral traits are recognized.

Morphological Differences

Mycelial patterns differ between ectomycorrhizal and saprotrophic mushrooms. The former form hyphal mantles around rootles ("sheaths") that allow exchanging nutrients, water, and bioactive compounds (Smith and Read, 2008). Moreover, ectomycorrhizal mushrooms produce extramatrical mycelia and rhizomorphs of differing structures (Agerer, 2001) (Plate 7). The so-called exploration types are categorized according to their spatial outreach (Table 2).

Exploration types dynamically interact in the sense of competition and co-existence modulated by soil characteristics (Agerer, 2013). Some physiological features can be attributed to exploration types, e.g. the production of extracellular phenoloxidas by short- and medium-distance types (Agerer, 2001) or increased phosphorus uptake by long-distance foragers (Agerer, 2013). Nonetheless, the link between nutritional physiology and exploration type is not strict and often phylogenetically founded (Agerer, 2013).

Basidiomes of saprobic taxa are, on average, smaller than those of ectomycorrhizal mushrooms, probably because the latter obtain sufficient and reliable carbon from their hosts without directly investing in its uptake (Bässler et al., 2015).

Spore traits also show some guild-specific characteristics. Contrary to saprobic mushrooms, the ectomycorrhizal guild shows more (hydrophobic) ornamentation and less thick-walled spores, while pigmentation is equally distributed between the guilds (Halbwachs et al., 2015). However, the thick wall-melanized trait syndrome dominates in the saprobic guild, which could be an adaptation to wind dispersal and preferences for aggressive substrates. In the latter case, coprophilous taxa show a conspicuous

Plate 7 The predominant exploration types: A: contact (*Chroogomphus rutilus*), B: short-distance (*Hebeloma sacchariolens*), C: medium distance (*Cortinarius semisanguineus*), D – long-distance (*Suillus plorans*); bars A-C 1 mm, D 0,5 mm. A-D, source www.deemy.de, with permission.

Table 2 The main exploration types in ectomycorrhizal fungi and their foraging characteristics (subtypes omitted); contact type set at 0

	Relative space occupation	Example (see Plate 7)
Contact	0	<i>Chroogomphus rutilus</i>
Short-distance	1	<i>Hebeloma sacchariolens</i>
Medium-distance	2.5	<i>Cortinarius semisanguineus</i>
Long-distance	19	<i>Suillus plorans</i>

Note: Agerer, R., 2001. Exploration types of ectomycorrhizae. Mycorrhiza 11, 107–114. Weigt, R.B., Raidl, S., Verma, R., Agerer, R., 2012. Exploration type-specific standard values of extramatrical mycelium—a step towards quantifying ectomycorrhizal space occupation and biomass in natural soil. Mycological Progress 11, 287–297.

triple trait syndrome. Their spores are thick-walled, melanized, and larger than their non-coprophilous allies (Halbwachs and Bässler, 2020). The authors hypothesized that thick spore walls limit the spore volume left for nutrients needed for germination and that the general tendency within the agaricoid clade to produce thick-walled spores (Garnica *et al.*, 2007) could have facilitated the switch to a coprophilous lifestyle. The latter possess germ pores, which allows quick germination (Garnica *et al.*, 2007).

The more often occurring ornamentation in spores of the ectomycorrhizal guild has probably co-evolved with soil-dwelling arthropods. It increases the chances of the spores to hitch a ride and get in the vicinity of host rootlets to become established (Calhim *et al.*, 2018). Germ pores do practically not occur in the ectomycorrhizal guild (Halbwachs *et al.*, 2015), except for a few *Inocybe* and *Amanita* species, at least in Scandinavian countries (Knudsen and Vesterholt, 2012).

Physiological Differences

There are considerable differences in basidiome pigmentation between the saprobic (SAP) and the ectomycorrhizal (ECM) guilds. For one, ECM mushrooms in Europe are, on average, significantly darker than their mutualistic cousins, which is probably an important factor in thermal regulation (Krah *et al.*, 2019). Second, ECM basidiomes show 33% more often bright reddish hues (light purple to vermilion, saturation > 50%) compared to SAP mushrooms (α of χ^2 test < 0.001) (based on the data set of Krah *et al.*, 2019), a trait that is predominantly associated with repelling and toxic as well as free radical scavenging qualities (Gill and Steglich, 1987).

It seems plausible that ectomycorrhizal mushrooms invest more often in toxic metabolites than the saprotrophic guild when since the latter need to invest in a more complex enzymatic toolset (N. Arnold, pers. communication).

Behavioral Differences

As stated above, ectomycorrhizal mushrooms have more pronounced host preferences than, e.g., wood decomposers. The ecological implications are twofold. Host specificity blocks competition, as the host does not accept other fungal taxa. On the other hand, dispersal and reproduction of host-specific fungi are more constrained than in promiscuous taxa, which have a broad choice of hosts (Molina *et al.*, 1992). This may not be overly limiting because host stands tend to be monotypic, especially at higher latitudes (Perry *et al.*, 2013). At arctic biomes, ectomycorrhizal mushrooms tend to be more promiscuous, probably because resource constraints select for optimizing establishment opportunities (Botnen *et al.*, 2014). One would expect that ectomycorrhizal mushrooms would preferably fruit during the late season when carbon allocation from the hosts is highest (Högberg *et al.*, 2010). Another study looking at ectomycorrhizal fruiting phenology of the ca. 2300 mushrooms described in the Funga Nordica (Knudsen and Vesterholt, 2012) revealed that this is not the case. Ectomycorrhizal and saprotrophic mushrooms behave quite similarly; both show a bimodal fruiting pattern (Halbwachs, 2019) (Fig. 9).

This surprising result points to two mechanisms. (1) Many ectomycorrhizal mushrooms accumulate nutrients in their mycelia, which can be used to fruit early in the next year, (2) the conspicuous fruiting drop during July may be an adaptation of avoiding fungivorous insects (Boddy and Jones, 2008) such as Mycetophilidae and Muscidae being most abundant during June to July (in Canada: Bolduc *et al.*, 2013). It is speculated that this pattern may be a strategy to also avoid competing soil microbiota by entering a mycelial diapause during which the formation of primordia is suppressed.

Fig. 9 Fruiting phenologies of Scandinavian ectomycorrhizal (ECM) and saprotrophic (SAP) mushrooms.

Future Directions

This compilation of macrofungal traits reveals numerous speculations and deficits. Therefore, efforts need to be increased to close such gaps, above all:

- (1) Ancestral state analyses of traits relating to survival and reproduction, thus gaining a deeper understanding of trait functioning and syndromes.
- (2) Applying comparative genomics to study the genetic foundation of the high morphological and physiological diversities.
- (3) Investigating genets to elucidate trade-offs between mycelial and basidiome biomass of fungal guilds.
- (4) Mining and analyzing data on mushroom traits to clarify the adaptive significance of phenotypes in view of environmental challenges, especially survival and reproductive fitness.
- (5) Analysis of trait impacts on assemblages and ecosystem functioning.

The functional traits of Ascomycetes remain grossly understudied.

Introduction

Fungi are remarkably diverse, occur in virtually every type of environment, and affect the lives of other organisms in many different ways. Molecular studies suggest that there may be up to 3.8 million species of fungi today; however, only approximately 120,000 of them are formally described and named (Hawksworth and Lücking, 2017).

As carbon heterotrophs, fungi have evolved different nutritional modes and mastered various levels of cooperation with, and exploitation of, other organisms to acquire carbon (Dighton and White, 2017). Many degrade organic compounds such as lignin and cellulose and, through this recycling, return minerals to the soil and CO₂ to the atmosphere (Baldrian and Valášková, 2008; Hatakka and Hammel, 2010). Others partner with bacteria (Devau *et al.*, 2018), or team up with algae and cyanobacteria to form lichens (Büdel and Scheidegger, 2008), while still others enter into symbioses with plants (Brundrett and Tedersoo, 2018). Fungi have also evolved intimate relationships with animals (e.g., fungus-growing ants; see Chapela *et al.*, 1994); some even thrive within the animal, in anaerobic environments (Trinci *et al.*, 1994). On the other hand, parasitic fungi negatively affect the performance of other organisms and, as pathogens they are causative agents of many diseases (Harper and Krings, 2020).

Although the earliest reports of fossil fungi date back more than 150 years e.g., (Unger, 1847), the fungal component has been largely ignored until recently when interpreting fossil ecosystems. However, already the scattered historical evidence indicated that fungi were drivers of many crucial ecosystem functions also in the past. Paleontologists today take increased effort to document fossil fungi and assess the roles they played in the environments in which they lived. As a result, there is an increasing body of literature on fossil fungi, including studies that document complex levels of biological interaction.

Documentation of fossils is the only method to gain appreciation for the diversity of fungi through geologic time (Taylor *et al.*, 2015). Because this contribution is nested within the section “Macroscopic Fungi”, which covers the Ascomycota and Basidiomycota with large fruiting bodies, it focuses on the fossil record of these two fungal lineages. The examples presented are not meant as an exhaustive review, but rather to demonstrate the types and quality of the evidence present. The fossil record of lichens is also briefly surveyed because these life forms today typically comprise members of the Ascomycota and Basidiomycota as mycobiont.

Fungal Evolution

The origin of the Fungi is estimated at between 660 Ma and up to 2.6 Ga ago based on molecular clock data and paleontological evidence [for the oldest (putative) fungal fossils, see Bengtson *et al.*, 2017; Loron *et al.*, 2019; Bonneville *et al.*, 2020; and the survey by Krings *et al.*, 2017b], and the divergence of the fungus-animal lineage from the plant lineage at between 780 Ma and up to 2.5 Ga ago (Lücking *et al.*, 2009; Berbee *et al.*, 2017).

The earliest fungi were aquatic. Just when these organisms first colonized the land surface remains an enigma, and how this arrival corresponds with the evolution of land plants an even further perplexing problem (Taylor *et al.*, 2015). There is evidence to suggest that fungi arrived on land approximately 1.0 Ga ago, when land plants had not yet evolved and the terrestrial ecosystems consisted of no more than biofilms and microbial mats made up of cyanobacteria in addition to various other microbes (Beraldi-Campesi, 2013). Nevertheless, these primeval ecosystems were no doubt critical for the early diversification of fungal nutritional modes and life histories. Although one can only speculate about the events during the terrestrialization of plants some 515–485 Ma ago (Morris *et al.*, 2018), a mutualistic symbiosis between some alga and a fungal partner likely was one necessary prerequisite to the establishment of plant life on land (Delaux *et al.*, 2015; Brundrett *et al.*, 2018). As terrestrial plants and ecosystems evolved, they progressively grew in stature, biomass, nutrient demand, and rooting depth to extensively colonize the continental land masses (Krings *et al.*, 2012). Molecular data and fossils indicate that the Fungi diversified, too, and readily became adapted to new types of environments and carbon sources. The largest morphological diversity in fungi today occurs in the Dikarya (i.e., Ascomycota and Basidiomycota), and is the expression of a long evolutionary success story (Fig. 1).

Modes of Fossil Preservation

The quality of information provided by fossil remains of Ascomycota and Basidiomycota depends on the way the fossils are preserved. For example, many types of propagules (e.g., conidia, ascospores) are durable structures that readily become preserved in a wide variety

Fig. 1 Summary of selected examples of ascomycotan and basidiomycotan fossils used in this article plotted on the late Precambrian and Phanerozoic stratigraphic chart. Stratigraphic chart based on Cohen *et al.* (2013 updated). Major milestones in the evolution of life on land are illustrated to place the information into a broader context. References corresponding to taxa and milestones can be found in Appendix 1.

of settings and, consequently, are often recovered as dispersed microfossils by acid digestion of sediments and rocks (Kalgutkar and Jansonius, 2000). While these remains can be used in stratigraphic studies based on palynomorph assemblages (e.g., Graham, 1962; Pieńkowski *et al.*, 2011), and some appear to have relevance also as proxy indicators of paleoecological events (e.g., Lageard and Ryan, 2013; Rampino and Eshet, 2018), they do not normally represent a major source of information on the biology of ancient fungi. Conversely, the complex fruiting bodies (basidiomata) of free-living macrofungi, especially Agaricomycotina, are highly informative

Plate 1 Examples of preservation types of ascomycotan and basidiomycotan fossils. biologically; however, most are short-lived and disintegrate within a few days (Nagy *et al.*, 2017), with next to no chance of becoming preserved in recognizable form. As a result, these structures are exceedingly rare as fossils. Common modes of preservation where fungal macrofossils might be found include amber, impression and compression, as well as petrification and permineralization (Taylor *et al.*, 2015). Moreover, there are several lines of indirect evidence that can be used to infer the presence of fungi in past ecosystems.

Amber

Amber, a solidified and fossilized tree resin produced by various conifers and angiosperms, is an excellent preservation medium that provides detailed insights into the diversity of soft-bodied organisms (Seyfullah *et al.*, 2018). Today amber is the most productive source of new information on fossil Ascomycota, Basidiomycota, and lichens (Kettunen *et al.*, 2018, 2019; Halbwachs,

Plate 4 Fossil basidiocarps. 2019b) (Plates 1–3). However, almost all amber comes from Cretaceous and Cenozoic strata, which is too geologically recent to record the origin or early evolution of most major lineages of fungi.

Impressions and Compressions

Impression fossils are negative reliefs that lack any organic remnants of the original organism. Some of the earliest reports of fossil macrofungi consisted of leaf impressions with various spots on them interpreted as fungi (e.g., Unger, 1847; Meschinelli, 1898) (Plates 1–1). Conversely, compressions are a type of preservation in which some (or all) of the original organic matter still remain, albeit usually altered in the form of coalification. Compressions of leaves may also show specks or black spots that have been interpreted as fungi (Pirozynski and Weresub, 1979) (Plates 1–2). Moreover, during the chemical preparation (maceration) of compressed leaves for cuticular analysis, fungi otherwise not seen become visible and, as a result, represent an expansive source of new information on associations of endophytic and epiphyllous fungi with ancient plants (e.g., Dilcher, 1965; Krings, 2001; Worobiec and Worobiec, 2017). In fact, our current knowledge of Mesozoic and Cenozoic epiphyllous Ascomycota is based primarily on chemically cleared leaf compressions.

Petrifications and Permineralizations

Petrifications and permineralizations are two types of preservation that provide exceptional resolution of (parts of) organisms that became immersed in water with high concentrations of dissolved minerals (e.g., silica, calcium carbonate) (Plates 1–5). Once the mineral is precipitated and hardened, the organism is entombed in rock and often faithfully preserved down to the finest anatomical details. The principal difference between petrification and permineralization is that the cell walls of the former are replaced by minerals, whereas they are still organic in the latter. Petrified or permineralized evidence of Ascomycota and Basidiomycota is known since the Devonian and Carboniferous, respectively, and usually occurs in the form of hyphae and propagules in cells and tissues of plant parts preserved by means of petrification or permineralization (Taylor *et al.*, 2015); however, there are also instances in which larger parts of these fungi (e.g., polyporalean basidiomes) are petrified or permineralized (e.g., Fleischmann *et al.*, 2007).

Indirect Evidence

One type of fossil that is not itself a fungus, but that may contain evidence of ancient fungi, is coprolites, fossilized animal feces or dung. Fungi are often well preserved in coprolites, and may provide information on environmental conditions, animal diet, and

Plate 5 Fossil gilled mushrooms in amber. Fig 1 *Palaeoagaricites antiquus*, Myanmar amber (Cretaceous, 15–20 Ma), bar 0.5 mm. sometimes even on fungal interactions (Plates 1–4). For example, coprolites of herbivorous dinosaurs have been described that contain remains of plant-parasitic fungi, and thus document the presence of this interaction in the fossil record (Sharma *et al.*, 2005).

Other indirect evidence occurs in the form of fossilized fungivorous animals. One interesting study infers the existence of diverse Early Cretaceous Agaricomycotina, as well as a specialized trophic interaction and ecological community structure, from the presence of diverse rove beetles (Staphylinidae) in amber from Myanmar (Cai *et al.*, 2016b, 2017). Moreover, several studies describe polypore fungus beetles from amber that add support to the hypothesis that polyporous mushrooms diversified during the Mesozoic (e.g., Soriano *et al.*, 2014; Cai *et al.*, 2016a; Yun *et al.*, 2018). Indirect evidence of the presence of fungi in certain paleoenvironments also occurs in the form of impression and compression fossils of mycophagous (feeding on fungi) animals. An excellent example of this is a fossilized derodontid beetle from the Jurassic of China (Cai *et al.*, 2014) (Plates 1–1).

Information on fungal evolution also comes from geochemical biomarkers (Marynowski *et al.*, 2013), as well as from molecular data obtained from extant organisms. For example, wood-degrading Ascomycota and Basidiomycota constitute one of the major drivers of carbon cycling in forest ecosystems today (White, 2003; Lonsdale *et al.*, 2008). Our current conception of the evolutionary history of these fungi and their roles in ancient ecosystems is largely derived from molecular studies, while fossils (e.g., silicified wood showing characteristic patterns of degradation and decay symptoms) have only been used in a limited sense (see review by Harper *et al.*, 2017).

Fossils of Ascomycota and Basidiomycota

Although some molecular clock analyses set the Ascomycota-Basidiomycota split at 1000–1490 Ma (see Lücking and Nelsen, 2018), which would place their origin in the Proterozoic, the geologic history of these two fungal lineages based on credible fossil evidence only extends back into the Paleozoic (Taylor *et al.*, 2015).

Ascomycota

The Ascomycota (sac fungi) is the largest group of extant Fungi, with ~65,000 described species that thrive as saprotrophs, parasites of plants, animals, and other fungi, and those forming symbiotic associations in lichens (see below); Ascomycota also form mycorrhizal relationships with plants (Tedersoo *et al.*, 2009). The principal character is the ascus, a sac-like structure (technically a meiosporangium) in which fusion of nuclei takes place that is followed by meiosis and the formation of non-motile ascospores (Pöggeler *et al.*, 2018). However, numerous ascomycetes are asexual (anamorphic), i.e., they lack a sexual phase (perfect stage); at least, a sexual stage has not been described or observed to date in these forms.

Chains of multiseptate spores and conidiogenous cells from the Silurian of Sweden are the oldest fossils to date thought to belong to the Ascomycota (Sherwood-Pike and Gray, 1985). The oldest structurally preserved fossil ascomycete is *Paleopyrenomycites devonicus* from the Lower Devonian Rhynie chert (Taylor *et al.*, 2005). This fossil occurs in leaf-like appendages of the

Plate 6 Compression fossils of Basidiomycota. Fig. 1 *Gondwanagaricites magnificus*, a gilled mushroom from the Cretaceous (113–120 Ma) of Brazil; gill remains well recognizable in top left portion, bar 5 mm. Fig. 2 Carbonized compression of an earthstar, Puebla/Mexico, Miocene to Pleistocene(?) (2–14 Ma?), possibly earlier (Lower Oligocene, ca. 30 Ma; Fig. 2), bar 5 mm. Reproduced from Magallon-Puebla, S., Cevallos-Ferriz, S.R., 1993. A fossil earthstar (Geasteraceae; Gasteromycetes) from the late Cenozoic of Puebla, Mexico. *American Journal of Botany* 80, 1162–1167.

early land plant *Asteroxylon mackiei* and consists of perithecia characterized by ostiolate necks protruding from the host epidermis through stomatal pores. Lining the interior of the perithecium are paraphysis interspersed with asci containing up to 16 ascospores.

Mesozoic and Cenozoic deposits have yielded abundant remains of Ascomycota (Taylor *et al.*, 2015); noticeable are several permineralized specimens (e.g., Mindell *et al.*, 2007; Bronson *et al.*, 2013), amber fossils of fruiting bodies (ascocarps or ascomata), including *Paleomorchella dominicana*, the first fossil of a morel (Poinar, 2016), and *Xylaria antiqua*, a fossil attributable to the family Xylariaceae (Poinar, 2014), both preserved in Miocene amber from the Dominican Republic, as well as records in Eocene Baltic amber of asexual reproductive structures of anamorphic fungi with probable affinities to the present-day genera *Periconia*, *Penicillium*, and *Scopulariopsis* (Tischer *et al.*, 2019).

Equally noticeable is the diversity of hyphae, fruiting bodies (e.g., thyriothecia, pycnidia), and hyphopodia (i.e., outgrowths from the mycelium that attach the fungus to the host) of microthyriaceous fungi on leaves. The vast majority of these remains have been obtained through maceration of compression fossils (e.g., Dilcher, 1965; Sun *et al.*, 2015; Bannister *et al.*, 2016), but there are also a few specimens in amber (Poinar, 2018). For the most part, the nutritional modes of fossil leaf-inhabiting fungi remain unknown; however, some authors note morphological similarities to modern plant pathogens such as *Asterina*, *Vizella*, and *Trichothyria*, thus inferring the nutritional mode as parasitism (Taylor *et al.*, 2015).

There is also fossil evidence of other types of organismal interactions involving members of the Ascomycota, much of which is preserved in Cretaceous and Cenozoic amber. For example, from lower Eocene amber from India, Beimforde *et al.* (2011) report an ectomycorrhizal fungus, *Eomelanomyces cenococcoides*, which closely compares to an extant member of the Dothidiomycetes. An interesting case of parasitism occurs in the form of a spectacular specimen of a fungus described as *Paleophiocordyceps coccophagus*, which was a parasite of Cretaceous scale insects (Sung *et al.*, 2008). This fossil provides the oldest compelling evidence of animal parasitism by fungi and is characterized by several synnemata emerging from the head of the host. Another case of animal parasitism comes from the Eocene and documents adaptive manipulation of ants by a parasitic ascomycete in the form of stereotypical death grip scars preserved in compressed angiosperm leaves (Hughes *et al.*, 2011). An interaction involving an ascomycete is also evidenced by a *Claviceps*-like sclerotium (*Palaeoclaviceps parasiticus*) that occurs on a grass floret entombed in Burmese amber (Poinar *et al.*, 2015). This fossil establishes the existence of intricate interactions between the ascomycete family Clavicipitaceae and flowering plant family Poaceae in the Early-mid Cretaceous. Moreover, Poinar *et al.* (2015) suggest that, if animals ingested the infected grass, they may have felt the effects of the psychotropic compounds produced by the fungus. Hallucinogenic substances produced by fungi often cause aversion for this fungus (Camazine, 1983), or they incite the intoxicated vector to erratically move around, thereby dispersing the spores of the fungus more effectively (Boyce *et al.*, 2019).

Resin exudates provide plants with protection against parasites and phytopathogenic microorganisms; however, some highly specialized fungi are also known to grow exclusively on these exudates (Beimforde and Schmidt, 2011; Beimforde *et al.*, 2017). The presence of resinicolous ascomycetes of the genus *Chaenothecopsis* in Eocene Baltic and Oligocene Bitterfeld ambers documents that these ascomycetes were already well adapted to their special ecological niche by the Eocene, and their morphology has since remained remarkably constant (Tuovila *et al.*, 2012). Baltic amber has also yielded an exquisite example a springtail overgrown by conidiophores of the fossil fungus *Aspergillus collembolorum* (Dörfelt and Schmidt, 2005). A second fossil *Aspergillus* comes from Dominican Republic amber and occurs in the form of tufts of catenulate chains of conidia covering the abdomen of a fly (Thomas and Poinar, 1988).

Basidiomycota

The Basidiomycota constitutes a major phylum of the kingdom Fungi and, with today more than 31,000 described species, are second in species numbers to the Ascomycota (He *et al.*, 2019). The diagnostic trait is sexual reproduction via meiospores that develop on projections of a club-shape structure termed the basidium (Coelho *et al.*, 2017). Another feature generally attributed to the Basidiomycota is the clamp connection, a hyphal protrusion that develops at cell division to facilitate maintenance of the dikaryon condition by providing a bypass for one of the nuclei (Plate 3).

The oldest generally accepted basidiomycete fossils with this feature occur in a structurally preserved fern stem from the Mississippian (Lower Carboniferous) of France, and comprise abundant septate hyphae with clamp connections that pass from cell to cell (Krings *et al.*, 2011) (Plate 3–1). Similar hyphae in a Middle Pennsylvanian (Upper Carboniferous) fern rhizome from North America have been named *Palaeancistrus martinii* (Dennis, 1970). Development of hyphal branches from clamp-connections, which is a common feature among certain modern basidiomycetes (Routien, 1948), has been documented for both these Carboniferous forms. Slightly younger, Early Permian hyphae with clamp connections have been discovered in a tree fern root mantle from Germany (Krings *et al.*, 2017a) (Plates 3–2, 3) and in a gymnosperm stem from China (Wan *et al.*, 2017). Mesozoic evidence of clamp connections comes from the Triassic of Antarctica (Osborn *et al.*, 1989), and Cenozoic clamp-bearing hyphae have been documented in Miocene amber from Sumatra (Halbwachs, 2019a) (Plates 3–4). Silicified gymnosperm wood degraded by wood-decaying fungi from the Permian and Triassic of Antarctica show irregular areas lacking cells, and septate hyphae with clamp connections (Harper *et al.*, 2017). The decay pattern in these fossils is comparable in appearance to present-day rots caused by basidiomycetes. Basidiomycota have also been identified as the causal agents for decay patterns in conifer wood specimens from the Jurassic of Argentina (Sagasti *et al.*, 2019) and the Cretaceous of China (Tian *et al.*, 2020) based on the presence of clamp-bearing hyphae in the decayed areas of the wood.

Molecular clock data have been used to suggest that the complement of enzymes necessary in lignin degradation evolved in fungi during the Early Permian, and that the decline of organic carbon at the end of the Carboniferous was directly correlated to the evolution of fungal lignin-degradation (Floudas *et al.*, 2012). Most, however, dismiss this hypothesis and regard the decline of

coal at the end of the Carboniferous as a result of a combination of climatic and tectonic factors (Nelsen *et al.*, 2016). Moreover, the oldest persuasive fossil wood showing disease symptoms suggestive of wood-degrading fungi comes from the Upper Devonian (Stubblefield *et al.*, 1985), and thus predates the age estimate given by Floudas *et al.* (2012) for the evolution of fungal lignin degradation by roughly 75 million years.

Fruiting bodies of Basidiomycota (basidiocarps or basidiomata) are exceedingly rare (or rarely recognized) as impression or compression fossils; however, there are quite a number of specimens preserved in amber and as permineralizations. Foremost among the Basidiomycota with a somewhat more extensive fossil record are the polypores (bracket fungi, conks), a morphologically heterogeneous assemblage of more than 1000 extant species in many families. Basidiomata of these fungi are often persistent (sometimes for several years) and possess a robust texture (Cléménçon *et al.*, 2012), and thus are more likely to become fossilized than other types of basidiomata (Plate 4). Although there have been some reports of polyporous basidiomata from the Paleozoic and early Mesozoic (e.g., Herzer, 1895; Hollick, 1910; Fohrer and Simon, 2002, 2003), most of these specimens have subsequently been discounted or reinterpreted as other organisms (e.g., Kiecksee *et al.*, 2012). On the other hand, Cenozoic deposits have yielded numerous persuasive specimens of fossil polypores, including *Trametes eocenicus* from the Eocene of Bohemia (Knobloch and Kotlaba, 1994), *Parapolyporites japonica* (Tanai, 1987) from the Miocene of Japan, *Ganodermites libycus* from the Miocene of Libya (Fleischmann *et al.* 2007), and *Ganoderma adspersum* from the Miocene of the Netherlands (Fraaye and Fraaye, 1995).

The fossil record of gilled mushrooms is almost entirely comprised of specimens preserved in amber (Poinar, 2016) (Plate 5). However, the most remarkable recent discovery is *Gondwanagaricites magnificus*, a fossil mushroom from the Lower Cretaceous of Brazil that does not occur in amber, but rather is preserved as a mineralized replacement in laminated limestone (Heads *et al.*, 2017) (Plate 6). The oldest amber fossil of a gilled mushroom, *Palaeoagaricites antiquus* from the Lower Cretaceous of Myanmar, consists of a portion of a cap, 2.2 mm in diameter, with 16 radial furrows (Poinar and Buckley, 2007). The systematic position of *P. antiquus* remains unresolved; however, morphology and habitat (conifer trunks) suggest affinities with the genera *Mycena*, *Marasmius* or *Collybia*. Several 1 cm-sized gilled mushrooms are known from Eocene amber of the Dominican Republic. One of them is *Coprinites dominicana*, a fossil believed to have affinities with the modern genus *Coprinus* (Poinar and Singer, 1990), while another, *Protomycena electra*, is similar to present-day members of the genus *Mycena* (Hibbett *et al.*, 1997). *Aureofungus yaniguaensis* is the third gilled mushroom known from Dominican amber (Hibbett *et al.*, 2003). Other fossil gilled mushrooms are more difficult to accurately place within a phylogenetic framework. One of them is *Archaeomarasmius leggetti* (Hibbett *et al.*, 1997), known from Cretaceous amber from East Brunswick, New Jersey (USA), which appears similar to the extant genera *Marasmius* and *Marasmiellus*.

Fossils attributable to other lineages of the Basidiomycota have also been described, including *Lycoperdites tertarius*, a member of the Gasteromycetes (puffballs) that is based on a set of 23 basidiomata at different stages of maturity, all preserved in a single piece of late Oligocene–early Miocene Mexican amber (Poinar, 2001). Another fossil gasteromycete, *Geastrum tepexensis*, is a compression fossil of an earth star from the Miocene–lower Pleistocene of Mexico (Magallon-Puebla and Cevallos-Ferriz, 1993) (Plate 6).

Lichens

Lichens are mutualistic associations of fungi and algae or cyanobacteria, or both, with body plans (thalli) and physiological properties that are different from either of the partners (Büdel and Scheidegger, 2008). The fossil record of lichens is exceedingly incomplete and includes only a few bona fide examples older than Cretaceous (Lücking and Nelsen, 2018). The crux of the matter is that the presence of both partners must be demonstrated to establish the existence of a fossil lichen. Furthermore, some degree of stable interdependence between the partners needs to be present. Most pre-Cretaceous fossils, interpreted as lichens or lichen-like associations, fail one or both of these criteria.

Early Devonian rocks from the Welsh Borderland have yielded *Cyanolichenomycites devonicus* and *Chlorolichenomycites salopensis*, two charcoalified bona fide lichen thalli that display thallus anatomies, similar to present-day heteromorous lichens (Honegger *et al.*, 2013). The thallus of *C. devonicus* is composed of a cortex several cell layers thick and a medulla of septate hyphae and presumed colonies of *Nostoc*-like cyanobacteria. On the other hand, fractured sections of *C. salopensis* show septate hyphae intermixed with globose cells thought to represent a green alga morphologically comparable to the common extant lichen photobiont *Trebouxia*. Perhaps the most widely known fossil interpreted as a lichen is *Winfrenatia reticulata* from the Lower Devonian Rhynie chert in Scotland (Taylor *et al.*, 1997). Specimens occur in the form of superimposed layers of parallel hyphae, the uppermost of which are folded vertically into loops that form a pattern of ridges and depressions. Extending from the walls of the depressions are hyphae that form a three-dimensional network of lacunae. Coccoid cyanobacteria surrounded by a prominent sheath regularly occur within the lacunae of the hyphal net. However, Lücking and Nelsen (2018) recently have questioned the lichen nature of *W. reticulata*, and suggested the fossil rather represents a cyanobacterial colony with fungal hyphae growing through it.

One of the few Mesozoic fossils believed to represent lichens is *Daohugouthallus ciliiferus*, an impression from the Jurassic of China of a small thallus composed of elongate primary axis that give rise to lateral and terminal branches (Wang *et al.*, 2010) (Plate 7–1). Filiform appendages morphologically resembling cilia arise from the thallus. On the other hand, *Honeggeriella complexa* from the Lower Cretaceous of British Columbia, Canada, is a permineralized bona fide lichen thallus that consists of a thick upper

Fig. 2 Selected fossil lichens plotted on the late Precambrian and Phanerozoic stratigraphic chart. Stratigraphic chart based on Cohen *et al.* (2013 updated). ¹Accepted and ambiguous statuses of fossil lichens is based on Lücking and Nelsen (Tab. 23.1). References corresponding to taxa can be found in Appendix 2. Reproduced from Lücking, R., Nelsen, M.P., 2018. Ediacarans, protolichens, and lichen-derived *Penicillium*: A critical reassessment of the evolution of lichenization in fungi. In: Krings, M., Harper, C.J., Cúneo, N.R., Rothwell, G.W. (Eds.), *Transformative Paleobotany: Papers to Commemorate the Life and Legacy of Thomas N. Taylor*. London, San Diego, CA, Cambridge, MA, Oxford: Elsevier/Academic Press Inc. pp. 551–590.

Fig. 3 *Prototaxites* in a reconstructed Devonian landscape, visualized by Geoffrey Kibby; image courtesy Geoffrey Kibby, British Mycological Society.

cortex and a slightly thinner lower cortex, both constructed of thick-walled hyphae that are described as forming a plectenchymatous structure (Matsunaga *et al.*, 2013). The medulla contains globose cells interpreted as the photobiont. The interaction between the photobiont and mycobiont is evidenced by narrow hyphae and appressoria on the surface of the photobiont cells. While the mycobiont is most likely ascomycetous, the nature of the photobiont is difficult to interpret.

While there have been relatively few reports on Mesozoic lichen fossils, there are many more from the Cenozoic, most of which are based on specimens in amber (Hartl *et al.*, 2015) (Plate 7–2). For example, more than 150 lichen fossils recently have been identified from Eocene European amber (Kaasalainen *et al.*, 2017), including several forms that hosted lichenicolous (lichen-inhabiting) microfungi (Kaasalainen *et al.*, 2019). This discovery is interesting because lichenicolous fungi live exclusively on lichen thalli, and their nutritional modes range from parasitism to commensalism (Rambold and Triebel, 1992). Another study of lichen-inhabiting fungi in Paleogene amber indicates that the fossil associations are essentially identical to their modern analogs, thus suggesting that the origin of this relationship must extend back much further, likely to the Mesozoic (Kettunen *et al.*, 2016).

An excellent example of the exquisite preservation of lichens in amber is *Anzia electra*, a small thallus characterized by prominent spongiostrium (i.e., a layer of anastomosing hyphae on the lower surface of certain lichens, not effective in attachment) cushions reported from Eocene Baltic amber (Rikkinen and Poinar, 2002). The fossil belongs to *Anzia* sect. *Anzia*, the closest living relatives of which are found in east Asia and eastern North America, thus suggesting that *Anzia* sect. *Anzia* once was widespread in North America, Europe, and Asia, but later became extinct in Europe.

Two fossil thalli assignable to the lichen family Parmeliaceae have been described in Oligocene-Miocene amber from the Dominican Republic (Poinar *et al.*, 2000). One of them, *Parmelia ambra*, is a foliose thallus with dichotomously organized lobes, and rhizines arising from the lower surface. The second, *P. isidiiveteris*, is characterized by sinuate lobes with multiple, unevenly scattered isidia. Another lecanoralean lichen preserved in Dominican amber is *Phyllopsora dominicanus* (see also Plate 7–4), characterized by a squamiform to subfoliose thallus with the overlapping squamules each approximately 1.0 mm wide (Rikkinen and Poinar, 2008). Finally, Baltic and Bitterfeld amber has yielded fossils of lichens displaying alectoroid morphologies (Kaasalainen *et al.*, 2015), as well as calicioid fungi and lichens, which all can confidently be assigned to modern genera, including *Calicium*, *Chaenotheca*, *Chaenothecopsis*, and *Phaeocalicium* (Rikkinen, 2003; Rikkinen *et al.*, 2018).

Nematophytes

There are numerous fossils in the Silurian and Devonian for which the biological affinities remain unknown; some of these have variously been interpreted as fungi. This is especially true of the nematophytes, a group of organisms constructed entirely of interlaced tubes (Kondas, 2018). The largest nematophyte, *Prototaxites* (Fig. 3), occurs in the form of compressed or permineralized trunks, some of which are 1.25 m in diameter and > 8 m long, and are constructed of three size classes of septate and non-septate tubes or hyphae and, in certain sections of the trunks, there are what are interpreted as growth increments.

The most comprehensive study suggests that this fossil may have had affinities with the Basidiomycota (Hueber, 2001); its heterotrophic nutritional mode is also supported by isotopic analysis (Boyce *et al.*, 2007; Hobbie and Boyce, 2010). While Hueber's (2001) interpretation of *Prototaxites* as a huge basidiomycete fruiting body figures prominently in the literature, there are also several other hypotheses that have been advanced, including some type of marine alga, a rolled-up mat of a liverwort, a representative of an extinct lineage of organisms that lacks modern analogs, and some type of lichen surveyed by Taylor *et al.* (2010). Moreover, a petrified *Prototaxites* specimen from the Lower Devonian Rhynie chert in Scotland has recently been used to interpret this form as a member of the Ascomycota with inoperculate, polysporous asci lacking croziers (Honegger *et al.*, 2017).

Future directions

The preceding paragraphs indicate that there is a remarkable abundance of fungal remains in the fossil record. However, systematic studies of fungal lineages based on fossils are rare, due primarily to inherent problems connected with the incompleteness of the fossil record of the fungi. Moreover, when fungi were reported in the past they were rarely placed within a broader context. During the last 35 years, however, there has been an increasing awareness of fossil fungi and the pivotal roles they played in ancient ecosystems, which has been stimulated by a generally growing scientific interest in the microbial world and the interrelatedness of all organisms today. There are multiple approaches and avenues of investigation that require an understanding of fossil fungi. We believe that the solution to many important questions pertaining to the evolutionary history of fungi and characteristics of ancient ecosystems can be answered through collaborative and synergistic research efforts between mycologists, ecologists, chemists, and paleontologists, as well as perhaps a few other specialists, to fully integrate the fossil record of these organisms with modern approaches, such as geochemistry, experimental paleontology, fungal genomics, and phylogenetic analysis, and with the record of the organisms with which the fungi have interacted throughout geologic time. For example, most amber fossils represent organisms that once lived together in complex forest ecosystems ("amber forests"). Amber fossils, therefore, not only provide insights into the morphology of different types of organisms, but also yield valuable direct and indirect evidence of organismal associations and interactions, such as fungus gnats and mushrooms, that can best be assessed by collaboration of specialists from different areas of expertise.

The Cultivation of Macrofungi

Introduction

Fungi interact with other organisms in ecosystems as decomposers and mutualistic or pathosistic symbionts, providing a number of ecosystem services (Millennium Ecosystem Assessment, 2005; Wallace, 2007). The main ecosystem services to which fungi contribute include nutrient recycling in the biogeochemical cycle (Gadd, 2007), soil health (Frac *et al.*, 2018), CO₂ storage (thanks to the fungi's contribution to the development of the tree component) (Leake, 2001), as well as the use that man has made of it in the food, medical and industrial fields (Brown, 2019; Comandini and Rinaldi, 2020; Gargano *et al.*, 2017; Hall *et al.*, 2007; Hall and Zambonelli, 2012a,b; Palanivel *et al.*, 2010; Polizeli *et al.*, 2005; Wasser, 2014). Especially in the food field the parts of fungus generally used are the sporomata or fruiting bodies in other words, the macrofungus that is visible to the naked eye.

Although macrofungi are a small part of the wide Kingdom of Fungi, they have a very high socioeconomic value for different human populations worldwide. Indeed, several macrofungal species were at first collected and consumed as wild products, and later they were cultivated and exploited for edible and/or medical purposes. The main species known worldwide are: button mushrooms (*Agaricus bisporus* (J. E. Lange) Imbach), porcini mushrooms (*Boletus* spp.), oyster mushrooms (*Pleurotus* spp.), morel mushrooms (*Morchella* spp.), truffles (*Tuber* spp.), Reishi (*Ganoderma* spp.), and Shitake (*Lentinula edodes* (Berk.) Pegler).

Unfortunately, not all macrofungal species are easily cultivable, and some species still need to be harvested as wild mushrooms. Probably the most famous example in the world is *Tuber magnatum* Picco (Italian white truffle), whose cultivation still remains very difficult, despite the extensive efforts of researchers around the world (Zambonelli *et al.*, 2015). In addition to the *T. magnatum*, there are many highly prized species consumed in many parts of the world, for which it would be interesting to develop and improve cultivation techniques, such as *Cordyceps* spp., *Tricholoma matsutake* (S. Ito & S. Imai) Singer (*ex T. nauseosum* (A. Blytt) Kytöv.), *Boletus* spp., *Lactarius* spp., *Suillus* spp., and *Amanita* spp. (Hall and Wang, 1998; Winkler, 2008). Today, the main cultivated species are saprobes (i.e., decomposers), which grow mainly on woody organic substrates. However, in the last century, thanks to the development of mycological, agronomical, and biomolecular knowledge, the cultivation of mycorrhizal mushrooms has also become a reality, in particular some truffles species, such as *Tuber melanosporum* Vittad., *Tuber aestivum* (Wulfen) Pers, and *Terfezia* spp., and some epigeal species, such as *T. matsutake*, *Lactarius* spp. (Chevalier and Desmas, 1977; Mannozi-Torini, 1981; Martin *et al.*, 2010; Morte *et al.*, 2012; Palenzona, 1969; Rubini *et al.*, 2014; Wang *et al.*, 2012; Yamanaka *et al.*, 2020). These achievements made the cultivation of mycorrhizal species a concrete economic reality in different rural areas in the world, such as Spain, France, Italy, New Zealand, and the United States (Di Piazza *et al.*, 2013; Guerin-Laguette *et al.*, 2009; Hall and Zambonelli, 2012a,b; Lefevre, 2008; Pacioni and Lamolinara, 2011; Trappe *et al.*, 2009; Reyna and Garcia-Barreda, 2014; Serrano-Notivoli *et al.*, 2016; Zambonelli *et al.*, 2017).

In recent decades, the boost of biotechnologies has propelled the cultivation of macrofungi for enzyme productions (Fazenda *et al.*, 2008), bioremediation of polluted environments (Meharg and Cairney, 2000) and biomaterial productions for green building (Appels *et al.*, 2019; Girometta *et al.*, 2019), as well as for medical and nutraceutical purposes (Phan *et al.*, 2012; Wasser, 2014). More recently, due to the growing need to develop a circular economy, some authors have proposed to cultivate mushrooms in the agricultural supply chains to "closing loops" (Banasik *et al.*, 2017; Grimm and Wösten, 2018; Yang *et al.*, 2016), in order to create virtuous cycles with very low impacts.

Undoubtedly, owing to fungi heterogeneity, it is not easy to assess the state of the art of macrofungi cultivation, because many species are exploited for different purposes, some of them connected to popular traditions and some connected to restricted areas of the world.

Due to the different methods of cultivation and management, saprotrophic and ectomycorrhizal fungi are often treated in different ways, so that the economic data are often fragmented not only geographically but also according to the type of cultivation. For example, there is a limited number of saprotrophic species distributed and used all over the world that are common to different areas. Precisely for this small but widely used group of species, in 2013 the global trade of mushroom industry was estimated to be about \$63 billion, where the major revenues (54%) are related to cultivated edible mushrooms (Royse *et al.*, 2017).

The purpose of this chapter is to give an overview about the huge world of macrofungi cultivation, addressing the main aspects related to the main cultivated species, cultivation techniques and information about biotechnological applications.

Cultivation of Saprotrrophic Species

Cultivated mushrooms are often saprotrophic macrofungi species able to grow on decaying organic matter. Most of them preferably decompose plant residues as a carbon source. This characteristic makes these fungi essential for the carbon cycle in natural ecosystems and particularly suitable for human cultivation (Stamets, 1994, 2005). Among the "saprotrophic obligated or facultative" mushrooms there are species difficult to cultivate due to their needs, for example some species belonging to genera *Cordyceps* (Raethong *et al.*, 2020) and *Morchella* (Liu *et al.*, 2018). For these cases, more in-depth studies are needed in order to

identify the trophic needs that allow for completion of the life cycle to optimize the process for sporomata production. Despite these particular cases, many other species can be successfully cultivated. Today 90% of the saprotrophic species cultivated worldwide belong to 5 genera: *Lentinula*, *Pleurotus*, *Auricularia*, *Agaricus* and *Flammulina* (Royse *et al.*, 2017). Regarding the technical aspects of the cultivation of macrofungi, the first step is to select a standardized substrate for cultivation of the target species. Once the substrate has been selected, the cultivation process is relatively simple and allows you to carry out one to more production cycles per year. Conversely, for the cultivation of symbiotic macrofungi the inoculation of the mycelium on a host plant is mandatory, making the management and development of symbiotic species much more difficult and slower.

The cultivation industry of saprotrophic macrofungal species is distributed worldwide. There are 3 main macro areas of production in the world: (1) Asia (in particular China, India and Japan); (2) Europe (Poland, Spain, France, Italy, and the Netherlands); (3) the United States of America. In these areas is concentrated 90% of the world's cultivation, processing and marketing of mushrooms (Royse *et al.*, 2017).

Among the species cultivated, due to its worldwide distribution and resilience *Pleurotus ostreatus* (Jacq.) P. Kumm. is the most studied species of mushroom, and it can be considered a sort of "model-species." *P. ostreatus* is probably the most studied because it is quite resistant and its laboratory and industrial management is rather simple. *P. ostreatus* is cultivated and studied for various purposes such as food, nutraceutical, biomaterial and bioremediation (Appels *et al.*, 2019; Girmay *et al.*, 2016; Sánchez, 2010; Vaverková *et al.*, 2018; Yang *et al.*, 2016; Yang *et al.*, 2019). These multiple uses testify to the great versatility of these organisms.

Main Steps

The cultivation of saprotrophic macrofungi depends on the specific trophic requirements of the selected species, the facilities available, the technologies applied in the process, and the purpose of cultivation (such as scientific, medical or food). Therefore, these aspects must be carefully considered before starting a cultivation. In general, any type of process of saprotrophic macrofungi cultivation involves five fundamental phases: (1) isolation; (2) substrate preparation; (3) inoculum; (4) incubation; (5) cultivation; (6) harvest and transformation. These phases, detailed in the following paragraphs, should be adapted to the specific situations.

Isolation

Isolation of the mycelium in axenic culture is essential for cultivating any macrofungal species. The mycelia of the most common species (e.g., *Agaricus*, *Pleurotus*, *Lentinula*, etc.) can be found quite easily because they are traded by several companies that produce mushrooms or by other companies in the agri-food sector. For less common species or for other scientific purposes such as carrying out molecular or biochemical study or making comparative studies between strains of different species, it is necessary to isolate mycelium in axenic culture directly from wild sporomata. For this purpose it is necessary to take portions of mycelium from fresh sporomata by operating in conditions of maximum sterility, using a laminar flow hood. The most common media used for the isolation of mushrooms are Potato Dextrose Agar (PDA), Malt Extract Agar (MEA) and Oatmeal Agar (OA); the recipes of the most common media are found in all the main manuals of mycology, such as Gams *et al.* (1987).

The main steps of isolation from fresh sporomata can be summarized as follows:

- (1) Collect fresh and healthy sporomata (not attacked by insects or other parasites).
- (2) Remove a portion of mycelium from the innermost part (in sterile conditions).
- (3) Place the portion collected on an agarized nutrient medium (PDA, MEA, OA).
- (4) Incubate in a thermostat (24°C for many species) and check the growth daily for possible contamination.
- (5) In case of contamination by other fungi or bacteria it is necessary to transfer part of the developed mycelium into a new petri dish. Repeat this operation until the pure culture is obtained.
- (6) Transfer the mycelium onto an agar slant tube and store at 4°C or with long-term preservation methods.

Long-term preservation of the isolated strains is an essential issue for any mycology laboratory and for any industry wishing to work with living fungal strains. Throughout scientific history preservation techniques have evolved to reach high levels of technological sophistication for the best long-term preservation of fungal strains. The long-term preservation of macrofungi is in some cases more difficult as they grow as mycelium and often they do not produce forms of resistance. However, in recent years, some authors have indicated different protocols for preserving at -80°C different mycelia from white-rot fungi (Voyron *et al.*, 2009) and truffles (Piattoni *et al.*, 2017), and have tested ultra-low freezing (-120°C) on *Ganoderma lucidum* (Leonardi *et al.*, 2018). These indications about long-term preservation methods are very precious for building banks to collect strains of particular interest.

Substrate, inoculum and incubation

The preparation of the substrate is a basic step for a successful cultivation. Minge Duggar (1904) more than 100 years ago highlighted differences in the colonization rate, mycelial texture and sporomata morphology of fungal species grown on different material. For this reason, the composition of the substrate must be assessed according to the nutritional needs of each cultivated species. Recently, several authors (Haneef *et al.*, 2017; Raethong *et al.*, 2020) investigated how the characteristics of the different substrates affect the physicochemical properties of the mycelium during its development. These findings open a new scenario for exploitation of macrofungal cultivation to make biomaterials (Appels *et al.*, 2019; Girometta *et al.*, 2019). Suitable substrates need balanced nutrients, proper humidity and homogeneous, compact but aerated structure, preferably with high surface-to-volume

ratio. An appropriate level of water activity is necessary to activate properly hydrolytic and oxidative enzymes to trigger the metabolic activity and enable mycelial colonization.

Regardless of the type of application, the substrates must be placed in heat-resistant plastic bags to be autoclaved. A proper amount of spawns must be prepared on different substrates such as grains, bran, cereals, sawdust and shavings. Once the sterilization phase is over, when the substrates have reached room temperature again, it is possible to proceed with the spawn inoculum. The substrates inoculated must be incubated for a period ranging from 20 to 120 days, depending on the specific needs of the inoculated species.

Cultivation and harvest

In this phase the well colonized substrates need to be placed in the plant facility to trigger primordia generation. Fruiting is a very delicate phase; it is necessary to maintain the environmental parameters stable in particular, to keep temperature and relative humidity within the ranges that allow the mycelium to develop primordia and bring them to maturity. These parameters vary according to the cultivated species, but for many species temperatures range from 18°C to 26°C and the relative humidity must be maintained around values of 80%–90% (Ferri *et al.*, 2007). Sudden changes in temperature or relative humidity during this phase can cause production decline or even the loss of all products. For these reasons, several factors must be taken into account when arranging for cultivation in the plant, such as the specific requirement of the species, the type of cultivation to be undertaken, and the climate of the area where the cultivation takes place. We classify the plants into three different types: free/open field, semi-controlled and controlled management. Based on the different plants, we have three different levels of control of the environmental parameters that influence development and consequently the collection of sporomata, as shown below.

- Free/open field: same conditions as in nature; the substrates are planted in natural or semi-natural environments that mimic the natural conditions of growth and development of the species. Ripening and harvesting period is identical to natural conditions.
- Semi-controlled: cultivation takes place in a protected environment (e.g., greenhouses, shadders, cultivation tunnels) where only a few parameters are monitored and partially controllable. Ripening and harvesting period longer than natural conditions.
- Controlled management: cultivation takes place inside incubation cells where it is possible to fine-tune all the parameters that influence growth. Ripening and harvesting can take place cyclically regardless of seasonal cycles.

Pests and Adversities of Cultivated Saprotrophic Mushrooms

Macrofungi, as well as other cultivations, are threatened by pests that can lower the quality of the product and reduce the final mushroom yield. The micro-environmental conditions inside of the cultivation area during the growing phase (in particular temperature and high relative humidity) can lead to the onset of rapidly spreading infections that can compromise the cultivation. Thus, attention must be paid to preventing the spread of pathogens, especially in intensive installations in closed and semi-closed environments. Arthropods and other microfungal species are the main threats to macrofungal cultivation, but there are also less well-known cases of contamination caused by bacteria and viruses.

Among the most common pests affecting cultivated macrofungal species on a world scale, we highlight the adversities of *Agaricus bisporus* caused by sciarid flies, for example *Lycoriella auripila* Winn and *Lycoriella Ingenua* Dufour (Grewal, 2000; White, 1997), which lay their eggs inside freshly pasteurized or inoculated compost. These flies cause double damage, as the larvae feed on the substrate, and the adults can act as vectors for many other diseases. The *Diptera* belonging to the genus *Megaselia* are often also vectors of fungal pathogens in *A. bisporus* cultivation (Jess and Schweizer, 2009). Among fungal-induced pathologies *A. bisporus*, like other cultivated fungi, is very susceptible to attacks of *Verticillium* spp. and *Trichoderma* spp., in particular *Trichoderma harzianum* Rifai (Kosanović *et al.*, 2013).

Also, *Pleurotus ostreatus* is susceptible to different pathologies caused by organisms of different origin; the most common fungal infection is caused by species belonging to genera *Mycogone*, *Trichoderma* and *Fusarium* (Ferri *et al.*, 2007). Since *P. ostreatus* is a widely cultivated species, different studies have also evaluated possible solutions for preventing its diseases. For example, studies have focused on the sensitivity of different *Trichoderma* pathogenic species to prochloraz (Innocenti *et al.*, 2019), and other research demonstrates the possibility of using *Aureobasidium pullulans* (de Bary) G. Arnaud as a biocontrol agent against the species *Trichoderma pleuroti* S. H. Yu & M. S. Park and *Trichoderma pleuroticola* S. H. Yu & M. S. Park without affecting the *P. ostreatus* growth and final production (Roberti *et al.*, 2019).

Among the better known threats to *Lentinula edodes* (Berk.) Pegler cultivation are the arthropod pests caused by coleoptera *Dacne picta* Crotch (Ohya, 1993; Sato *et al.*, 1998), *Lepidoptera*, for example *Paragona multisignata*, *Diomea cremata* (Yoshimatsu and Nakata, 2003; Yoshimatsu and Kawashima, 2016) and *Diptera*, in particular *Camptomyia* sp. The mechanisms of infection are not yet fully understood, but some authors hypothesize that the harm of green mould (*Trichoderma* spp) is caused by secondary attacks of these insects (Kim *et al.*, 2016; Wang *et al.*, 2016). In 1993 the mite *Luciaphorus auricularia* was identified as a pathogen of *Auricularia polytricha* (current name *Auricularia nigricans* (Sw.) Birkebak) and *A. auricula-judae* (Bull.) Quél. In China (Zou *et al.*, 1993) this mite can lead to the loss of up to half of the production.

It is clear that pathogens of cultivated macrofungi are numerous, and most of them are still unknown. In recent years, thanks to an increased environmental awareness and to the need to increase food safety, some researchers have started to test biological control agents against the most common threatening organisms, such as the microfungi of the genus *Trichoderma* and the sciarids belonging to the genus *Lycoriella*. For this purpose, two biofungicides, based on *Bacillus subtilis* and tea tree oil respectively, were

tested against several *Trichoderma* species, highlighting the efficiency of *B. subtilis* against all *Trichoderma* tested (Kosanović *et al.*, 2013). Concerning pests, the predatory mite *Hypoaspis miles* Berlese has shown great potential in protecting *A. bisporus* cultivation from the *Sciaridae* belonging to genus *Lycoriella* (Jess and Schweizer, 2009). These studies have proposed environmentally friendly alternatives to the use of traditional chemical products, stimulating research in this field aimed at limiting the use of synthetic products which, in addition to being harmful to the environment, are detrimental to the health of consumers.

Cultivation of Ectomycorrhizal Species

Ectomycorrhizal fungi (hereafter ECM), living in obligate symbiosis with woody plants, play a key role in forest ecosystems. Thanks to this close interaction, ECM fungi contribute to the development and improvement of multiple ecosystem services for communities living within and/or close to forest areas (Donnini *et al.*, 2013; Zotti *et al.*, 2013). For example, the edible ECM species are the source of valuable food products (*Amanita caesarea* (Scop.) Pers., *Cantharellus cibarius* Fr., *Boletus* spp, *Lactarius* spp, *Morchella* spp, *Rhizopogon* spp, *Terfezia* spp, *Tricholoma matsutake* and *Tuber* spp.). Some of these species are not only a source of food but also pillars on which the economies of several villages and small towns in rural areas worldwide are based (Wang and Hall, 2004). Due to the nature of this obligate symbiosis, ECM fungi are mainly harvested as wild products, because the cultivation of ECM is difficult and it has always been considered a kind of “magic secret”. For this reason, for many centuries ECM cultivation was limited to empirical evidence from natural history scholars who unfortunately were not yet aware of the details of mycorrhizal symbiosis (Dessolas *et al.*, 2007). Some of these empirical practices, providing good results, are still in use and are useful to improve and progress of cultivation techniques. Recently, for example, Murat *et al.* (2016) highlight how the empirical technique of “trapping truffles” seems to have positive effects on the production of *Tuber melanosporum* orchards. However, at the end of the seventeenth century, thanks to the first observation and descriptions of ectomycorrhizal structure (Frank, 1885), did rational research about the cultivation of macrofungal ECM begin. In fact, the discovery and description of ectomycorrhizal structure triggered a process that about 85 years later, at the end of the 1960s (1969), led to the cultivation of valuable ECM species, in particular truffles, in a rational way. The first data relative to the production of mycorrhizal plants with truffles were published in 1969 by Fontana and Palenzona. Today, thanks to decades of research in the mycological, biomolecular and agronomic fields, we can cultivate many ECM species for food purposes (Hall and Zambonelli, 2012a,b), forest restoration, decontamination from pollutants (Assad *et al.*, 2020; Futai *et al.*, 2008), and from their cultivation we can derive important positive effects on the ecosystem and the surrounding environment.

However, today the majority of ECM fungi cultivated are edible species. The best results have been achieved with the cultivation of different species of genus *Tuber*. Among the best-known examples we can mention *Tuber melanosporum*, grown mainly in Spain, France and Italy (Reyna and Garcia-Barreda, 2014; Samils *et al.*, 2008; Sourzat, 2017), though it has also been introduced in some areas in North America (Lefevre, 2012), Australia and New Zealand (Hall *et al.*, 2007), whereas *Tuber aestivum* is perhaps the most cultivated truffle species worldwide. Thanks to its ecological plasticity, *T. aestivum* is successfully cultivated in almost all of Europe – France, Italy, Spain, Portugal, Sweden, United Kingdom, Germany and Finland – with excellent results (Molinier *et al.*, 2016; Shamekh *et al.*, 2014; Stobbe *et al.*, 2013; Wedén *et al.*, 2009, 2013). *Tuber borchii* Vittad. is another less known species cultivated locally in Italy (Iotti *et al.*, 2016), while in North America among the native species of hypogean ECM *T. oregonense*, *T. gibbosum* are the most appreciated and sought-after species, and, although there is no ancient tradition, several initiatives have been underway in recent years aimed at enhancing and improving the visibility of these products that have a great potential (Lefevre, 2008, 2012). Unfortunately, as mentioned above, it is not yet possible to cultivate *Tuber magnatum* Picco rationally.

Also, the epigeal species are very difficult to cultivate; for example, the first report about the production of *Cantharellus* fruit bodies dates back to 1997 (Dannel & Camacho, 1997). This work also hypothesized the possibility of cultivating *T. matsutake*, which is another economically interesting epigeal species. Other epigeal ECM species successfully cultivated around the 2000s are *Lactarius deliciosus* (L.) Gray, *Lyophyllum shimeji* (Kawam.) Hongo (Wang and Hall, 2004). Many efforts have since been made to study the cycle of other species such as *Boletus* or *Amanita*, to develop methodologies and protocols to increase production in naturally productive areas (Águeda *et al.*, 2008). For example, several experiments have been carried out in northern Europe to stimulate production in the forests of the region, while in Spain and France, particularly in the so-called “mycoforests” of the Rone-Alpes region, forestry practices are applied that take into consideration the effects on the production of macrofungi (Büntgen *et al.*, 2017; Pierangelo and Rolland, 2014). Today only silvicultural practices are effective to stimulate the production of these species in areas that are already productive; this practice is called mycosilviculture (Savoie and Largeteau, 2011).

It is very difficult to estimate the economic income derived from ECM cultivation because the data available concerns only a few species, and often data are from both cultivated and wild products. Despite the paucity of the data, we can state with certainty that it is a large market capable of sustaining many people who live in different parts of the world, especially in rural areas. Below are some examples of what happens worldwide. For example, in Spain, the estimated annual production of the *B. edulis* species complex from the autonomous community of Castilla y León is 8500 tons, worth approximately € 38 million (Martínez-Peña *et al.* (2006–2008); Ortega-Martínez and Martínez-Peña, 2008). In Italy the satellite-activities of truffle cultivation are essential for sustaining several villages in the Apennine mountains (Donnini *et al.*, 2013; Iotti *et al.*, 2012). In France 80% of the production is still essentially in the southeast, mainly in the Drome, the Vaucluse and the Alpes de Hautes Provence, being the three principal departments (in 1999/2000 the national total was 30 tons, of which 27.4 came from the southeast and 3.6 from the southwest). Even if these data indicate a large market, the real value is likely to be much higher.

Ectomycorrhizal Plant Production

As already mentioned, to cultivate ECM mushrooms it is essential to plant trees inoculated with the desired species. Over the years, the research in the field of mycorrhized seedling production has gone through different methods of inoculating plant roots: in sterile, semi-sterile and non-sterile conditions (Repáč, 2011). Basically, mycorrhizal synthesis can be induced in three different ways: spore inoculation, radical approximation, and mycelial inoculation. Over the years, these techniques have been studied in the laboratory to be perfected and put into practice directly by specialized nurseries. Using well mycorrhized seedlings, the grower is only tasked with planting plants already inoculated. An interesting option among the three fundamental techniques is the one proposed by French researchers who, referring to ancient truffle-growing manuals, foresee the inoculation in situ (Dessolas *et al.*, 2007). The advantage of this method is that it no longer takes place in the laboratory but is done in the field when the plants are planted, reducing costs. However, this practice has been rejected in recent years by some authors, as it appears to have a high rate of contamination by other ECM species during the colonization process.

All of these techniques obviously have advantages and disadvantages, so it is always necessary to choose the most suitable technique according to the production needs, the availability of sporomata to produce suitable quantities of inoculum and the macrofungal species you want to use. The inoculation methods used for the production of mycorrhizal plants are described in detail below.

Spore suspension inoculum

The protocol of spore inoculation is one of the most widely used for the production of mycorrhized seedlings. Given the simplicity of the method it is probably the most ancient. In the past truffle hunters had empirically used this technique to prepare the inoculum to stimulate truffle production of potentially suitable plants. In the twentieth century, thanks to advances made by scientists, this method was standardized by researchers to make it more effective (Chevalier and Desmas, 1977; Chevalier and Grente, 1974; Chevalier and Poitou, 1990; Fassi and Fontana, 1967; Fontana and Palenzona, 1969).

The preparation of the seedlings (from seed or micropropagation) is made in semi-sterile conditions, in order to limit as much as possible the presence of antagonistic species. Mature and well-identified sporomata, previously sterilized, are grinded in order to obtain a mush of spores suspended in distilled sterile water; inoculation by immersion of the preparation obtained on the root systems of the young plants (Repáč, 2011). Through this method, the spores contained in the truffle, germinating near the root apparatus, will infect the roots of the plants. This process has an average duration of 6–7 months.

This method obviously presents several problems, since it is necessary that the sporomata of the selected species must be characterized by the production of a high quantity of fertile spores, and they must be available in abundant quantities without excessive cost. Even if mild sterilizations can be carried out, the microflora present in the sporomata and near the fertile parts could affect the success of the colonization. Therefore, it is difficult to obtain a homogeneous and repeatable result, because the success is affected by multiple factors arising from the quality of the material found. For example, unwanted species can be inoculated, especially when using production waste or cleaning residues from truffle cleaning. These products can often be mixed of different species, and therefore you could get different plants than you expect. Furthermore, several authors have pointed out that the sexuality of mycelium has a significant influence on the success of colonization and fructification; therefore, the choice of material and the preparation of the inoculum require careful preparation (Iotti *et al.*, 2016; Rubini *et al.*, 2014).

Spore-based inoculations have many advantages. The inoculum is relatively cost effective and easy to prepare, and it requires less time, no specialized equipment and less specialized training, compared with other methods. Spores are obtained by crushing whole sporomata (in the case of truffles) or only the mushroom hats (in the case of porcini or mushrooms with gills) using a mortar and pestle, an electric mill or a blender. To facilitate the grinding of fungal tissue, sterile water coupled with sand or other types of fine abrasive particles can be added to the crushing process.

Radical proximity

This method involves the use of a mycorrhized “mother plant”; it is very effective because it exploits the high infectivity of the hyphae produced by the active mycorrhizas (Iotti *et al.*, 2012). This method works well for those species that have low germinability of the spores and for which the mycelia have difficulty performing mycorrhizal symbiosis because they have low infectivity and suffer from competition with other mycelia (Gregori, 2002). For example, it is empirically exploited in some areas of Italy by truffle hunters who take seedlings and suckers from already productive areas to plant them in other areas. This method saves the purchase cost of the ascomata, which is very high especially for fine species, so that it can have a positive impact on the price of mycorrhization on the seedlings. However, to make this method effective over time, it is important to maintain a healthy of mycorrhization in the “mother plants” by having highly trained personnel monitor the state of mycorrhized roots and check for the presence of competing species.

In order to be able to carry this method out on a large scale there are certainly high initial costs, as a large number of mother plants need to be owned. However, if the mother plants are managed well over time, the gains should make it possible to justify the high initial planting costs.

Mycelium-based inoculum

This procedure is probably the most recent and technologically advanced one; it involves the isolation of mycelium in axenic culture and its multiplication in vitro in special nutritive soils. Once satisfactory quantities of mycelium have been obtained, it is used to inoculate young seedlings by adding it to the soil. Mycelium has been considered the most suitable source of inoculation

for infecting plants with ECM fungal strains (Marx and Kenney, 1982). However, the large-scale nursery application of this type of inoculum depends heavily on the saprobic potential of the fungal species of interest and its ability to produce large amounts of mycelium under axenic conditions.

Compared to previous methods, this method makes it possible to produce seedlings free of foreign fungi and with a high degree of mycorrhization. In addition, through this method it is possible to inoculate with specific fungal genotypes specially selected on the basis of specific needs, for example, infectivity and affinity to the host plant, high tolerance of, or ability to degrade, particular pollutants, and resistance to high environmental stress. Among the negative aspects, however, it should be noted that this method requires specific, rather expensive structures and instrumentation, and highly specialized personnel. Moreover, not all fungi have mycelia vitality after isolation and in vitro cultivation; in fact, many studies are carried out to find new culture media to make it easier to isolate and multiply the species that are more difficult to cultivate in the laboratory. One of the first protocols related to this technique is that of Molina and Palmer (1982), but unfortunately this is time-consuming and difficult to apply. Today, on the basis of past protocols, improvements have been made and many steps have been optimized. In fact, it is possible to perform mycorrhizal synthesis with mycelial cultures for many edible ectomycorrhizal ascomycetes and basidiomycetes, both in greenhouse and in vitro (Águeda *et al.*, 2008; Danell and Camacho, 1997; Endo *et al.*, 2014; Giomaro *et al.*, 2005; Zambonelli *et al.*, 2008). However, it is widely used only for some edible ECM species such as *Lactarius deliciosus* and *Tricholoma matsutake*. In 2016 the first data on the production of *Tuber borchii* ascomata were published 8 years after the planting of plants inoculated with pure crops, highlighting the possibility of using this technique to produce truffle plants instead of the more widely used spore inoculum (Iotti *et al.*, 2016, 2012).

Adversities of Cultivation of ECM Mushrooms

On the basis of what has been described, it is clear that the cultivation of ECM fungi, due to their symbiotic mutualism, still presents particular difficulties that require the deepening of knowledge about several problems in order to find effective solutions. One of the main problems is certainly due to the high affinity of different species with the host plant. In fact, as it is known for each a plant species there are many fungal species that can do symbiosis, and, since it is not a pathological aspect, it is impossible to notice this competition without specific morphological and/or molecular investigations of the root system. In this case the competition between mycelia could lead to considerable economic damage in terms of lack of production.

Examples of competition between mycelium, for example, are reported within truffle cultivations where more adaptable and less valuable species can threaten the success of a truffle plantation. For example, the competitiveness of *Tuber brumale* Vittad. against *Tuber melanosporum* and *Tuber aestivum* was recently highlighted in a 14-year-old plantation that sowed seedlings inoculated with these three truffle species in adjacent plots. The results confirm the competitiveness of *T. brumale* against *T. aestivum* and *T. melanosporum* due to its great ability to colonize the soil around its ectomycorrhizae. However, its competitiveness is limited to the transept and has never been found within the *T. melanosporum* plot. These results show that, under optimal conditions for *T. melanosporum* and *T. aestivum*, the greatest risk of contamination with *T. brumale* is due to incorrect greenhouse activity (Ori *et al.*, 2018).

The Cultivation of Macrofungi for New Biotechnology

Recently, fungi were fruitfully exploited in a number of fields different from the food industry. Many researchers proposed to employ this kind of organism for bioremediation applications (mycoremediation) and biomaterial production (Appels *et al.*, 2019; Fazenda *et al.*, 2008; Girometta *et al.*, 2019; Meharg and Cairney, 2000).

Mushrooms can bioaccumulate and biodegrade a high range of organic and/or inorganic toxic compounds by means of the production of specific enzymes (e.g., lignin peroxidases and manganese peroxidases) and secondary metabolites (e.g., organic acids; Kapahi and Sachdeva, 2017; Vishwakarma, 2019). Not only saprotrophic but also white/brown rotting and ectomycorrhizal (ECM) fungi are well known in bioremediation technologies (Gadd, 2007; Vishwakarma, 2019). Elevated concentrations of toxic metals and radionuclides can often occur in sporangia of saprotrophic and ECM fungi in many polluted environments (Gadd, 2007; Liang and Gadd, 2017), favoring plants' colonization and playing a central role in the biogeochemical cycles of a site (e.g., *Thelephora terrestris* Ehrh.; Cecchi *et al.*, 2019). Conversely, white-rot fungi are well known to degrade petroleum hydrocarbons not only in terrestrial environments but also in seawater (e.g., *Phanerochaete chrysosporium* Burds., *Pleurotus ostreatus*, *Trametes versicolor*, *Bjerkandera adusta* (Willd.) P. Karst., *Lentinula edodes*, *Irpex lacteus* (Fr.) Fr.; Kumar *et al.*, 2018; Prasad, 2017). Furthermore, the surprising performance of mushrooms in biotechnology has been explored to produce new biomaterials for packaging (Haneef *et al.*, 2017), thermal and acoustic insulation (Girometta *et al.*, 2019) and a broad variety of design objects and furniture (e.g., <https://grow.bio/>), and to replace plastic in electronics (Vasquez and Vega, 2019) and produce biodegradable "bioblocks" from agricultural waste (Joshi *et al.*, 2020).

Conclusions

People have always attempted to cultivate different species of mushrooms, including the valuable hypogean species mainly for food interests and recently for the possible exploitation in the field of bioremediation. Today, the best results in the world involve the cultivation of different saprotrophic species, whereas ectomycorrhizal species, with a few exceptions, are difficult and expensive

to cultivate. The studies devoted to improving fungal production and to making possible cultivation of new species of fungi for different purposes are in progress all over the world. Currently, issues related to mycoselviculture and growth incentives are generating a great deal of debate, since these techniques aim to increase the production of those species whose development cycles we are not able to control.

Introduction

Macrofungi (also referred to collectively as “mushrooms”) have been an important component of human food for thousands of years, with the earliest reports of macrofungi consumption coming from Spain (18,700 years ago), China (5000–6000 years ago) and Egypt (4600 years ago) ([Chang, 2006](#); [Power et al., 2015](#); [Straus et al., 2015](#); [Zhang et al., 2015](#)). Because of their pervasive use in dishes across disparate cultures, there is also a long history of developing mushroom cultivation techniques to ensure steady supply. The earliest attempts to cultivate macrofungi were found in Asia, followed by efforts in Europe and eventually in North America. The artificial cultivation of *Auricularia* sp was described 1400 years ago from China in *Tang Materia Medica* by Tang Sugong. In Europe, evidence suggests that France introduced the first cultivated mushroom in the 17th century ([Zhang et al., 2015](#)).

Given the long history of human consumption of macrofungi, it is only in recent times that we have described and truly embraced macrofungi as a staple part of global human cuisine, as shown by an exponential increase in production and trade of mushrooms. This rising recognition, awareness and use has also led to the consumption of more species and spurred technological development for cultivated species as well as research on the ecology and sustainable management of wild species, the majority of which cannot be cultivated.

We present an overview of cultivated and collected edible macrofungi and their trade and commercial value. We discuss challenges faced by growers and traders as a result of increasing market demands as well as the importance of mushrooms to the food industry. Despite a long history of collecting wild mushrooms, uncertainty and confusion still exist on which species can be safely eaten. We also discuss a new classification system aimed at resolving different opinions and assessing published case reports ([Li et al., 2021](#)).

Types of Edible Macrofungi

Edible macrofungi can be classified into three trophic groups: ectomycorrhizal, saprobic and parasitic. They originate from two main sources: species that are wild-harvested and those that are cultivated. Generally speaking, it is only the saprobic fungi that are cultivated, though new techniques are emerging for the partial cultivation of several ectomycorrhizal species. Approximately 60 edible species are commercially cultivated out of a potential 100 species identified by [Chang and Miles \(2004\)](#).

Wild edible mushrooms are mainly saprobic or ectomycorrhizal. Edible parasitic fungi are few in number; perhaps the most common species, *Armillaria mellea*, mainly colonizes the wood of tree species. Edible parasitic fungi also include several plant pathogens, including maize smut and sorghum smut ([Boa, 2004](#)). Ectomycorrhizal fungi form a symbiotic association with tree roots, exchanging nutrients assimilated from the soil for photosynthetically derived carbohydrates from the host tree ([Deckmyn et al., 2014](#)).

The most widely cultivated macrofungi are *Agaricus bisporus*, *Lentinus edodes*, *Pleurotus* species, *Flammulina velutipes*, *Auricularia auricula* and *Volvariella volvacea* ([Kabel et al., 2017](#); [Chang and Wasser, 2012](#); [Bellettini et al., 2019](#); [Zhang et al., 2013](#)). Some progress has been made in the cultivation of ectomycorrhizal fungi, though this is only manageable for a few species and cannot be conducted independent of a host tree. Well-known examples include *Tuber melanosporum* ([Hall et al., 2007](#)), and *T. indicum* ([Hu et al., 2010](#)). Young trees must first be inoculated with the truffle fungus. Once the ectomycorrhiza form, the host trees are transplanted and managed in truffières, akin to fruit orchards. It can take up to 10 years for trees to become productive.

Wild Macrofungi

Wild edible macrofungi have diverse morphological features and shapes ([Fig. 1](#)). Some are typical mushrooms with a stalk and cap (sometimes referred to by scientists as “agarics”), while others are fan-shaped, ball-like, disc-like, saddle-shaped, cup-like and so on. Widely consumed types include typical mushrooms, boletes, chanterelles and truffles, though species preferences vary considerably throughout the world.

A recent study reported the existence of 2189 wild collected edible species ([Li et al., 2021](#)) of which 2006 can be consumed safely, and a further 183 species that require pretreatment before safe consumption or were associated with allergic reactions. Harvesting

<i>Craterellus cornucopioides</i>	Europe	(Peintner <i>et al.</i> , 2013)
<i>Lactarius deliciosus</i>	Europe	(Peintner <i>et al.</i> , 2013)
<i>Morchella esculenta</i>	Europe	(Peintner <i>et al.</i> , 2013)
<i>Cantharellus formosus</i>	North America	(Pilz and Molina, 2002)
<i>Cantharellus subalbidus</i>	North America	(Pilz and Molina, 2002)
<i>Hydnum repandum</i> , <i>Hydnum umbilicatum</i>	North America	(Pilz and Molina, 2002)
<i>Tricholoma magnivelare</i>	North America	(Pilz and Molina, 2002)
<i>Morchella</i> sp.	North America	(Pilz and Molina, 2002)
<i>Leucangium carthusianum</i>	North America	(Pilz and Molina, 2002)
<i>Tuber gibbosum</i>	North America	(Pilz and Molina, 2002)

commercial macrofungal species from the wild, such as matsutake (*Tricholoma* sp.), boletes (*Boletus* sp.), truffles (*Tuber* sp.), morels (*Morchella* sp.) and various *Lactarius* species (e.g. *L. deliciosus*) is commercially lucrative in many countries and provides essential income for collectors and their families (Boa, 2004; de-Román and Boa, 2006; Yeh, 2000; Cai *et al.*, 2011). The most harvested and traded wild edible macrofungi in Asia, Europe and North America are presented in **Table 1**.

Many studies have confirmed the economic importance of wild edible macrofungi as key non-timber forest products (NTPs) (Cunningham and Yang, 2011; Christensen *et al.*, 2008; Zambonelli *et al.*, 2012). Accelerating demand has led to concerns about excessive harvesting and associated environmental damage, both affecting the sustainability of wild collections (Mortimer *et al.*, 2012). Harmful practices, including raking the ground surrounding trees for emerging mushrooms, may already have affected production for some of the most-sought after species. Exports of *Tricholoma matsutake* and Bolete species both decreased from 2010 to 2015 due to diminishing yields (**Table 2**). Management schemes have attempted to establish sustainable guidelines for harvesting wild edible macrofungi (Yu and Liu, 2005; Luoma *et al.*, 2006; Pilz and Molina, 2002), but ensuring good practices and policing laws aimed at regulating harvests are not straightforward. In response to concerns about sustainability, many countries have adopted corresponding measures; in Europe, for example, 16 countries have enacted relevant legislation and others have implemented guidelines (Peintner *et al.*, 2013). Setting limits for how much can be collected could potentially contribute to increased productivity (de-Miguel *et al.*, 2014). An interdisciplinary approach to sustainable management developed for *Thelephora ganbajun* took into consideration the needs of farmers and policies aimed at protecting local habitats and ecology (He *et al.*, 2011). de-Miguel *et al.* (2014) found that in pine forests, macrofungal production has a direct relationship with forest management: intense schemes (higher rate of felling) increased total mushroom yield, while non-intense forest management schemes (lower rate of felling) decreased total mushroom yield.

Some studies have looked more carefully at harvesting intensity (Hopping *et al.*, 2018). Along a longitudinal transect, Ruiz-Almenara *et al.* (2019) collected wild mushrooms, for seven months in the year, with each collection lasting two days, and continuing for 5–9 years, and found that this did not affect the diversity and distribution of species. Egli *et al.* (2006) found no correlation between intensity of harvesting and yields or species richness. Trampling had a temporary reduction on mushroom numbers, though allowing sites to “rest” enabled population recovery. Pilz and Molina (2002) also indicated that harvesting wild will not impair resources in the short term. We agree that reasonable macrofungi harvesting does not necessarily negatively impact macrofungal yield and species richness, but overharvesting can impair both (Evans, 1997). One possible explanation is because harvesting macrofungi involves only

Table 2 Total foreign export volume and value of *Tricholoma matsutake* and *Boletes* from 2010 to 2015 in Yunnan Province

Year	Total output of foreign export (/t)	Total foreign exchange (/10000 dollar)	Total output of foreign export (/t)	Total foreign exchange (/10,000 dollar)
2010	1203.15	4724.73	10,499.15	7511
2011	764	5750	12,431	9178
2012	964	4859	9142	6675
2013	781	4058	7708	5921
2014	708.9	3837	7041.3	4852
2015	432.4	2455	8366	4965

Note: Adapted from Wang, T.-T., Zhao, C.-Y., Chen, X., Guo, X., Wu, S.-R., 2017. Analysis and recommendations on current status of Yunnan Province edible fungi industry during the “12th Five Year” period. *Edible Fungi of China* 36, 70–75.

collecting sporocarps, leaving underground mycelium and the surrounding habitat relatively undisturbed. Thus, habitat protection and management is critical to macrofungal production and distribution (Evans, 1997). The ultimate aim of managing wild edible macrofungi is to achieve sustainable production, yet there continues to be a severe lack of related knowledge in many countries. Due to marked differences in the types of habitats inhabited by wild edible macrofungi, working closely with local communities will be needed in future to develop site-specific management strategies through rigorous and participatory scientific inquiry (Brown *et al.*, 2018).

Cultivated Macrofungi

The 12 species (out of 60 overall) that are commonly cultivated at scale are: *Agaricus bisporus*, *Lentinus edodes*, *Pleurotus eryngii*, *Volvariella volvacea*, *Hericium erinaceus*, *Auricularia auricula-judae*, *Ganoderma lucidum*, *Grifola frondosa*, *Flammulina velutipes*, *Tremella fuciformis*, *Pholiota microspora* and *Coprinus comatus*. The two main cultivation methods consist of growing the fungi on substrates or using submerged fermentation. Most commercial edible macrofungi are cultivated in bags or using compost beds. The choice of substrate and cultivation technique has a strong influence on the nutritional content of mushrooms. Techniques are constantly being updated and improved, particularly in recent years, such as on *Ganoderma lucidum*, *Lentinus edodes* and *Schizophyllum commune* (Elisashvili, 2012). Nonetheless, growing mushrooms on substrates remains time consuming and labor intensive. Submerged fermentation is more rapid and capable of generating large quantities of mycelia and extracellular bioactive products usable as food ingredients and flavoring agents (Lu *et al.*, 2020).

The general cultivation process for edible macrofungi includes two phases: laboratory-based work (spore/sporocarp tissue isolation, pure culture, stock culture, spawn preparation) and cultivation in growing houses (culture media production, inoculation culture, cultivation management, spawn running and harvesting) (Lee *et al.*, 2015) (Fig. 2). Maintaining sterility during pure mycelia isolation and spawn production is crucial. Growth conditions need to be controlled as well, appropriately adjusting factors like temperature, relative humidity, oxygen, pests and diseases (Thawthong *et al.*, 2014).

Health and Nutritional Benefits Provided by Macrofungi

In addition to their culinary value, macrofungi can contribute significantly to the nutritive value of a meal. Macrofungi are rich in proteins, amino acids, vitamins and dietary fiber, also containing a wide array of compounds that provide health benefits. Macrofungi consumption can thus deliver manifold benefits to human health.

The protein content of macrofungi can be extremely high for a non-meat based food source, with a number of species reaching protein levels exceeding 30% (Table 3) (Kumar *et al.*, 2013; Valverde *et al.*, 2015; Sanmee *et al.*, 2003; Maga and Joseph, 1981). Macrofungi are also a good source of carbohydrates, with many species having carbohydrate levels above 50% (Table 3). Conversely, fatty acids and cholesterol content are relatively low, further enhancing their health benefits (Ribeiro *et al.*, 2009). Macrofungi are a natural source of many vitamins (B1, B2, B12, C, D and E) (Heleno *et al.*, 2010; Mattila *et al.*, 2001). Vitamin D is essential to human health and generally available as Vitamin D3, which is largely found in animal-based products, such as meat or eggs; however, research has shown that mushrooms can also be valuable source of Vitamin D2, D3, and D4 (Cardwell *et al.*, 2018). Wild-harvested mushrooms have higher levels of Vitamin D than cultivated mushrooms, as UV light is required for Vitamin D production in mushrooms (Valverde *et al.*, 2015). Thus, if cultivated mushrooms are exposed to an artificial source UV light, they have the potential to also produce vitamin D, thereby enhancing the food value of cultivated mushroom products (Cardwell *et al.*, 2018). Furthermore, macrofungi are rich in minerals (selenium, potassium, iron, copper, zinc, manganese) essential for a balanced diet (Sánchez, 2004). Selenium, commonly found in edible macrofungi, is an essential trace mineral important to maintaining a healthy immune system, improves fertility in adults and has also been linked with a reduction in the risk of cancer, thyroid disease and asthma.

Dietary fibers, which are carbohydrate polymers that show resistance to digestion and absorption by the human digestive tract (Alimentarius, 2015), play an important role in human health. Fibers are useful in preventing and treating diabetes as well as in mitigating cardiovascular disease and colon cancer (Kaczmarczyk *et al.*, 2012; Kendall *et al.*, 2010). The cell wall components of

Fig. 2 Macrofungi cultivation process.

macrofungi (chitin and polysaccharides like mannans and β -D-glucans) are not easily digested by the human digestive tract and thus comprise a form of dietary fiber (Cheung, 2013). Although the content of dietary fiber varies between macrofungal species (Table 3), eating macrofungi on a daily basis can provide up to 25% of the required daily dose of fiber for humans (Cheung, 2013).

Macrofungi are rich in essential amino acids such as threonine, leucine, isoleucine, methionine, lysine, tryptophan, histidine, phenylalanine and valine (Yuwa-amornpitaK *et al.*, 2020; Valverde *et al.*, 2015). Additional amino acids found in macrofungi include glutamic acid, aspartic acid and glutamate. Essential amino acids are vital to human health, as the human body cannot synthesize these amino acids and needs to receive them via a balanced diet. These amino acids are important for the building of proteins, transport of nutrients within the body and maintaining an effective immune system.

Traditional medicine systems have a long history of using benefits associated with macrofungi in the treatment of illnesses. Indeed, the list is extensive and increasingly recognized by modern medicine. *In vivo* and *in vitro* testing has indicated that macrofungi can be used in antitumor, cancer-related, hypoglycemia, hypotension, diabetes and cardiovascular treatments; macrofungi are also characterized by immunostimulatory, neuroprotective, anti-neuroinflammatory, cytotoxic, anti-hyperlipidemic, antifungal, antibiotic, antiviral, antioxidant and hepaprotective properties (Valverde *et al.*, 2015; Chang and Wasser, 2012; Finimundy *et al.*, 2013; Yu *et al.*, 2009; Zhang *et al.*, 2011). A comprehensive list of macrofungal species and associated medical benefits is shown in Table 4. Some well-known examples of the medical applications of macrofungi include *Ganoderma lucidum* (Reishi) in antitumor, antioxidant and antimicrobial treatments (Ferreira *et al.*, 2015); *Herichium erinaceus* (Lion's mane fungus) in nerve damage treatments, as it possesses neuroregenerative properties (Wong *et al.*, 2012); and *Cordyceps* sp. in diabetes treatments and to improve human immune systems, as well as the uptake of oxygen by the blood (Shashidhar *et al.*, 2013; Mehra *et al.*, 2017). Furthermore, *Inonotus obliquus* (Chaga) is an effective treatment against tumors, diabetes and cardiovascular disease (Balandaykin and Zmitrovich, 2015).

Economic Value and Social Perspectives of Edible Macrofungi

Edible mushrooms are cultivated in more than 100 countries (Gupta *et al.*, 2018). The global consumption of edible macrofungi is around 12.74 million tons and global production is estimated to reach 20.84 million tons by 2026 (Research and Markets, 2018). The macrofungi industry was valued at approximately \$63 billion in 2013, \$34 billion of which stems from cultivated edible macrofungi, \$24 billion from medicinal macrofungi and \$5 billion from wild harvested macrofungi (Royse *et al.*, 2017). Over 30 billion kg of macrofungi were produced in China in 2013 (China Edible Fungus Association, 2014), accounting for 87% of total global production. The rest of Asia produced about 1.3 billion kg, while the EU, the Americas, and other countries combined produced about 3.1 billion kg. Five main genera constitute around 85% of the world's macrofungi supply. *Lentinula* is the major genus, contributing about 22% of the world's cultivated macrofungi. *Pleurotus* constitutes about 19% of the world's output while *Auricularia* contributes around 17%. The other two genera, *Agaricus* and *Flammulina*, account for 15% and 11% of the volume, respectively. Currently, only 10 countries in the world exceed 100,000 tons of production, namely the United States, Japan, the Netherlands, South Korea, Poland, Vietnam, Spain, France, Thailand and the United Kingdom.

In European countries, truffles are a multi-million-euro industry. In France, Italy and Spain, truffles are foraged in natural forests and also cultivated in truffle farms. *Tuber melanosporum* production is estimated to be worth approximately 23.5 million USD annually in France (Escafre and Roussel, 2006), 8.8 million USD in Spain and 4.8 million USD in Australia (Duell, 2012). In the past decade, the price that farmers receive for one kilogram of *Tuber melanosporum* in Europe ranged from less than 176 USD to

more than 939 USD. The price for retail customers can be even higher; in Paris and London, it is not uncommon for prices to reach 2347–4695 USD per kg. This encourages European truffle farmers to sell directly to markets. Moreover, additional economic gains result from the impact of truffle sales on agritourism, local mycological gastronomy, value-added truffle products, truffle fairs and retail markets. In total, the economic impact of *Tuber* was estimated at 117 million USD per year in Italy alone (Gregori, 2007; Doménech and Barreda, 2014).

Many rural people in developing countries rely upon commercial harvesting of wild macrofungi as an important source of household income. For example, there is a strong tradition of collecting and consuming wild edible macrofungi in eastern Finland, a region where the Karelian people settled from Russia. Around 25% of Karelian families collect wild mushrooms and sell them at markets. Boa (2004) showed that total amounts sold in local markets can be considerable. In Malawi, money earned by local mushroom collectors is not insignificant, and local markets for wild edible macrofungi are currently expanding. In Turkey, around 11 tons of fresh *Lactarius deliciosus* are annually sold in 13 villages. The total annual value of four key wild edible species is around 100,000 USD (Boa, 2004). Perhaps the most notable example of the role that wild harvesting of mushrooms has on local economies can be seen in Yunnan Province of China. Households and, at times entire communities, can generate their annual

Table 4 Bioactive compounds extracted from edible macrofungi

income during the wet season, from the sales of wild mushrooms, with thriving towns being established around the key purpose of trading in mushrooms.

Seasonal Availability and Preservation

Wild mushrooms occur in natural habitats inside small fruiting windows, often during rainy season, leading to predictable seasonal availability for timing harvests. Fruiting conditions vary considerably across hemispheres and climatic conditions (Montoya *et al.*, 2014). For example, the fruiting season of *Tricholoma matsutake* lasts from July to October, in the Northern Hemisphere, in which the soil temperature needs to average 19°C and relative humidity around 80%, (Yamanaka *et al.*, 2020). *Tuber indicum*, however, fruits between August to November in the Northern Hemisphere (García-Montero *et al.*, 2010). Because of their transient but predictable pattern of occurrence, wild edible macrofungi are considered delicacies and typically associated with a brief, seasonal flurry of economic activity around their collection and sale (Garibay-Orijel *et al.*, 2006). Developing commercial cultivation schemes under controlled conditions extends the fruiting window of these rare commodities. Given the heightened worldwide demand for edible macrofungal consumption, farmers in less developed regions of the world are now well positioned to increase production of cultivated mushrooms, bolstering rural incomes and mitigating environmental strain associated with wild overharvesting (Zhang *et al.*, 2018).

The fruiting bodies of fresh wild edible macrofungi typically have a short shelf life (1–3 days) at ambient temperatures (Diamantopoulou and Philippoussis, 2015; Ruan-Soto *et al.*, 2017). To meet this challenge, techniques have been developed to preserve fresh fruiting bodies beyond this short period of edibility, particularly in the preservation of *Agaricus* sp, *Lentinus edodes* and *Pleurotus* sp (Akbarirad *et al.*, 2021). Preservation methods can be divided into two types: short-term preservation (cooling, minimal processing, packaging) and long-term preservation (freezing, canning, pickling, drying) (Diamantopoulou and Philippoussis, 2015). Preservation methods can be further divided into thermal preservation (drying, cooling), physical preservation (packaging, irradiation, pulsed electric field) and chemical preservation (washing, coating, ozone, electrolyzed water) (Fig. 3) (Zhang *et al.*, 2018). Modern industrial technologies have significantly improved preservation methods. However, local communities around the world continue to predominantly rely upon four traditional methods of macrofungi preservation: drying, pickling, freezing and canning (Ruan-Soto *et al.*, 2017).

Socio-Cultural Aspects of Macrofungi as Food

The concept of mycophilic and mycophobic peoples, countries and regions proposed by [Wasson and Wasson \(1957\)](#) has greatly influenced research and popular understanding of cultural attitudes and preferences for wild edible macrofungi. While it is a helpful concept for understanding cultural preferences, behaviors and depth of macrofungal knowledge, the concept is less useful in recognizing that behaviors and choices change over time. For example, local knowledge of safe-to-eat species can be easily lost as rural people migrate to urban centers, while new traditions can be introduced as people emigrate. Ukrainians who migrated to northeastern Argentina after World War 1 brought with them a vibrant tradition of collecting and eating wild macrofungi, infusing it into the weak existing local traditions.

Polish immigrants in the United Kingdom are carrying on their home tradition of visiting forests in late summer and autumn to seek out edible macrofungi in increasing numbers. The same applies to Italians and other “mycophilic” nationalities as they have been transplanted around the world. The acquisition of new eating habits involving wild macrofungi can also be reversed when reports of poisoning are widely published, especially through social media.

Simpler explanations for why some people do not eat wild macrofungi, despite local availability, also exist. [Svanberg and Lindh \(2019\)](#), describe how Swedes have greatly strengthened their predilection for wild macrofungi in the post-industrial era largely through informal educational and social events. Greater confidence in identifying species and the chance to gather “free food” led to behavioral changes. A loss of habitat and suitable tree species with edible ectomycorrhizal associations may also contribute to weak or absent traditions in a given area.

Much of our knowledge of local traditions around the collection and eating of wild macrofungi is anecdotal and poorly documented, though there has been a significant increase in ethnomycological studies (e.g., [Nanagulyan et al. \(2020\)](#) for Armenia

Table 5 Morbidity and mortality following consumption of wild mushrooms reported from different countries and their regions

2-Hospitalization of patients with macrofungi poisoning.

and Lucaj *et al.* (2021) for Lao PDR). The primary motivations for collecting wild edible macrofungi include earning money (Cai *et al.*, 2011) and self-consumption. Edible macrofungi comprise a valuable source of nutrition (Boa, 2004), particularly for poorer rural communities, or are simply a source of gastronomic intrigue and variety in middle- and higher-income countries. The harvesting of matsutake (*Tricholoma magnivelare*) in Bhutan (Namgyel, 2000) only attracted the attention of local people when the opportunity for commercial trade with Japan was identified.

The introduction of tree species to an area with novel edible macrofungi associates can boost local incomes as well as establish more positive attitudes toward mushrooms. *Pinus nigra* was used extensively in afforestation schemes in Castile Leon in Spain, introducing abundant and valuable harvests of *Lactarius deliciosus* (de-Román and Boa, 2004). The income potential of these chance occurrences is not fully understood, in part because the commercial harvesting of valuable species is unregulated in many countries and veiled in secrecy, driven in part by a desire to protect collection sources and avoid fees and taxes (Dyke and Newton, 1999). A stark contrast in attitudes to edible macrofungi in Finland (Härkönen, 1998) reflects the ethnic origins of collectors and

consumers. Those from Sweden have traditionally had a much weaker tradition of collecting and consuming wild mushrooms compared to those originally from Karelia, a region in neighboring Russia.

The direct nutritional value of wild macrofungi harvests to rural communities is also poorly understood. Yields are unpredictable, tightly linked with weather conditions, and the window of opportunity for harvesting fresh macrofungi is small. Some rural communities preserve excess harvests in oil or dry macrofungi, particularly *Boletus* and allied species, a practice common in China, Russia and countries in eastern and southern Africa with miombo woodland. In these circumstances, preserved macrofungi can offer diverse nutrients that are accessible in food-poor times of the year (Afonkin, 2013).

Food Safety

Food safety has been a hot topic for the assessment of human health all over the world. Although wild edible mushrooms have many benefits to human health, poisoning incidents caused by picking and consuming poisonous macrofungi continue to occur every year around the globe, posing a serious threat to human health. A number of accidents have been reported in Europe, north America and Asia (Chen, 2014). For example, in North America, according to the latest annual report on macrofungi poisoning issued by the North American Fungi Association, about 100 people are poisoned by eating poisonous macrofungi every year. In the Piemonte region of Italy, there were 177 macrofungi poisoning incidents involving 318 people from 2002 to 2009 (Zicari *et al.*, 2011). In Asia, there were 569 poisoning incidents from eating wild macrofungi from 2001 to 2010, and of these, 1920 people were poisoned and 10 died (Yamaura, 2013). Likewise, from 2004 to 2014 in China, there were 3701 poisoning incidents and 786 deaths (He *et al.*, 2019). The morbidity and mortality of wild macrofungi are summarized in the Table 5. The available data suggest that China, Russia and the Ukraine have the highest mortality rates from macrofungi poisoning. Mortality rates from macrofungi poisoning are also high in Belarus, Poland, Turkey, Iran, Nepal and Mexico. However, this must be seen in the context of an estimated total of 200–250 deaths occurring worldwide in any one year (Govorushko *et al.*, 2019).

Some species can only be eaten with careful cooking methods or pretreatment. For example, before cooking, *Bulgaria inquinans*, the fresh fruiting body must first be washed in clean water before being rubbed with light alkali water until all the black spores on the surface have been washed away. Additionally, *Bulgaria inquinans* contains a bioactive photosensitive toxin (Diisobutyl phthalate), which can produce allergic symptoms such as the swelling of the mouth and burning pain of the skin under sunlight when eaten without being properly cleaned (Bao *et al.*, 2019). It is thus necessary to clarify contradictory or ambiguous information to avoid future poisoning incidents. Furthermore, it is imperative to develop a structured definition of macrofungal edibility to strengthen knowledge and confidence in consuming wild species while also reducing consumer anxiety around edible fungi (Li *et al.*, 2021).

Besides innately poisonous macrofungal species, edible macrofungi can also be contaminated from outside sources, such as from the environment, during processing, degradation and spoilage. The most common outside sources of contamination are heavy metals, pesticides, processing contaminants, radioactive isotopes, microbial contamination, inherited toxins and allergens. Previous studies have indicated that many edible species of macrofungi can potentially accumulate high concentrations of heavy metals, of which mercury, cadmium, lead, and arsenic have received the most research attention. For example, *Lycoperdon perlatum*, *Macrolepiota rhacodes* and *Lepista nuda* have been identified as potent accumulators of lead (Kalač and Svoboda, 2000; Sesli *et al.*, 2008). *Boletus edulis*, *Marasmius oreades* and *Tricholoma georgii* can accumulate a high-concentration level of Cd and Hg (Kalač and Svoboda, 2000). Related research also found that approximately 26%–72% of arsenic toxicity was significantly reduced by cooking (Chiocchetti *et al.*, 2020). In addition, macrofungi are a perishable food, easily contaminated by other microbes; therefore, eating spoiled macrofungi should be avoided.

We propose six recommendations to address these issues: (1) industry, importers and restaurants should only trade or serve macrofungi that are widely known to be edible and correctly identified; (2) obligatory training for business operators that produce foodstuff with macrofungi or who import macrofungi should be enforced to prevent poisoning events; (3) food inspectors should have a general knowledge about which macrofungi are edible; (4) consumers should consume edible macrofungi, both fresh and processed, only when they are confirmed to be safe and labeled accordingly; (5) new tools for regulating trade and industry as well as for public food inspection should be developed; and (6) a list of guidelines informed by intelligent risk assessments for edible macrofungi should be generated, which can be used in accordance with general food safety requirements (Niksic *et al.*, 2016).

Conclusion

Macrofungi have been shown to be an important source of food and nutrition for humans, contributing to our health and development. Although macrofungi have been eaten by humans for thousands of years, it is only in recent history that the true value of macrofungi as a food has been embraced, as reflected in the massive upsurge in the production and trade of macrofungi. This increase is likely the result of gains made in our own understanding of the nutritional composition of macrofungi as well as the recognition of macrofungi as a functional food and as a positive contributor to human health. However, despite the widespread use of macrofungi as a food, knowledge gaps still exist around which macrofungi are considered safe and suitable to eat. Complicating the picture is that an element of cross-cultural subjectivity may influence determining the edibility of macrofungal species. This subjectivity may cloud the reality of what can and cannot be eaten. Thus, a concerted effort should be made to not

only further research the food safety aspects of macrofungi but also to present and refine a standardized system for categorizing the edibility of macrofungi.

Overview: Human Fungal Pathogens

Sirida Youngchim, Chiang Mai University, Chiang Mai, Thailand

Joshua D Nosanchuk, Albert Einstein College of Medicine, New York, NY, United States

Human pathogenic fungi are a major cause of morbidity and mortality, and the incidence of fungal diseases continues to rise and new fungal pathogens, including the identification of cryptic species, are emerging. Recent estimates of the incidence of fungal diseases conclude that there over 300 million people globally who develop a serious invasive infection every year and close to a billion individuals have cutaneous fungal diseases (GAFFI, 2018). Annual incidence estimates for leading invasive mycoses include ~700,000 invasive *Candida* infections, ~500,000 *Pneumocystis* pneumonias, ~250,000 patients with invasive aspergillosis, ~220,000 episodes of cryptococcal meningitis, and ~100,000 cases of histoplasmosis. Moreover, there are an estimated 1.5 million deaths annually attributed to fungal diseases (Bongomin et al., 2017).

General recognition of fungi as major human pathogens did not occur until the 1980s, and was associated with a marked increase in invasive mycoses linked to the HIV epidemic, the increased use of invasive procedures and intensive care units, and the administration of immunosuppressive drug therapies (Nucci and Marr, 2005). Moreover, increased global travel, climate change, and novel immunotherapies are contributing to the increased rates of fungal diseases. These chapter of the encyclopedia on human pathogenic fungi has over 40 chapters that broadly cover key concepts in the biology of human fungal pathogens, details major etiologic agents of human mycoses and disease syndromes, and reviews approaches to diagnosis and treatment of fungal diseases encountered in our healthcare systems.

Chapters are dedicated to the epidemiology of yeast and mold infections. Insights into epidemiology have led to life-saving interventions in specific patient populations, such as in various prophylactic antifungal regimens provided to transplant patients. However, the chapters also reveal areas of new risks for fungal diseases. For example, the advent of new immunomodulatory therapeutics being administered in cancer care as well as other diseases has led to specific alterations in immunological cascades that are placing those receiving these novel therapeutics at risk.

The chapters on specific pathogens as well as frequently encountered diseases, ranging from infections of the skin to the central nervous system, effectively present the biology of human pathogens and the disease processes that occur. Certain fungi, like *Candida albicans* and *Pneumocystis jirovecii*, are primary human commensals whereas the vast majority of fungal pathogens are acquired from the environment. The variety of human pathogenic fungi span three different phyla Zygomycota, Ascomycota, and Basidiomycota. Depending on the species, the pathogenic morphologies of these fungi can appear as molds, pseudohyphal forms, yeast or other unique structures, such as the spherules of *Coccidioides* species. These various morphologies are challenging to the host immune system, particularly in the setting of phase transition, where the immune cells are faced with structures that can be antigenically quite different from that originally acquired from the environment.

The chapters in this encyclopedia also highlights emerging and re-emerging fungi. The broad use of antifungals in humans, animal husbandry, and agriculture along with changes in climate, increased incursion of humans into new environments, and profound immunosuppression of certain patient populations have resulted in a surprising number of clinical cases of human mycoses by new or re-emerging pathogens. Examples in these chapters include *Candida auris*, a global threat due to its rapid emergence and resistance to antifungal drugs, and *Emergomycosis* species, which have also occurred globally. Molecular biology has also influenced this process as previously described single species have now been shown to actually consist of several cryptic and/or divergent species. For example, *Paracoccidioides brasiliensis* and *P. lutzii* diverged at least 30 million years ago, whereas the cryptic species with the *P. brasiliensis* complex evolved within the past few to 12 million years ago (Turissini et al., 2017). Furthermore, certain fungi have been renamed based on deeper analyses of genomes, such as the major fungal pathogen in Southeast Asia *Penicillium marneffei* becoming *Talaromyces marneffei* (Fig. 1).

Effectively diagnosing and managing of human mycoses is critical to the outcome of these diseases; yet, despite our current approaches for identifying and treating these diseases, mortality rates of invasive mycoses remain at ~40%. The chapters review the classic approaches to identifying fungi in clinical situations and also detail newer advances that are improving our ability to efficiently diagnose patients. Point of care tests, such as the lateral flow assay for cryptococcosis, are especially important in low resource countries. Molecular tests and applications of matrix-assisted laser desorption/ionization (MALDI) time-of-flight (TOF) mass spectrometer approaches have also accelerated our capacity to diagnose these complex diseases. Antifungal medications used for systemic therapy currently target either cell membrane (ergosterol) synthesis or stability, synthesis of cell wall beta-glucan, or RNA synthesis. Exceptions include the use of trimethoprim-sulfamethoxazole for treatment of pneumocystosis or paracoccidioidomycosis. Chapters in the encyclopedia review the mechanisms of action, the spectrum of activities of and resistance mechanisms to these drugs as well as their unfortunate toxicities. Additionally, a chapter presents information about new drug development, which is essential to improve our armamentarium for application to the care of patients with invasive mycoses. Harnessing the immune system to combat fungal diseases is an exciting area of study, and a chapter is presented that focuses on immunotherapy for fungal infections.

Fungal diseases remain a major scourge on humanity. Although investigators and healthcare providers have dramatically improved our knowledge about fungi and our capacity to care for patients with fungal diseases, an increased focus is necessary to

Fig. 1 The human pathogenic fungal pathogen *Talaromyces marneffei*. Fig. 1. Colony appearance *T. marneffei* on potato dextrose agar at 25°C (A) and brain heart infusion agar at 37°C (C). truly combat fungal infections, which too often are neglected in terms of public policy and research agendas (Rodrigues and Nosanchuk, 2020). The chapters on human fungal pathogens in this encyclopedia provide the reader with a broad and solid background on fungal biology and the diseases currently encountered.

Introduction to Fungal Pathogens and Antifungal Drugs

The discovery of penicillin by Fleming in 1928 was a breakthrough moment in the history of Medicine, showing that microorganisms can produce active compounds of medical use (Fleming, 1929). Since then, the development of effective antimicrobials has been a priority for the treatment of infectious diseases. The high impact that pathogenic microorganisms have in our society has resulted in the use of multiple drugs that have helped to control their incidence. However, there is still a great need to find new antimicrobial therapies to treat these diseases. Some examples are opportunistic fungal diseases, which have increased their incidence in our society due to the emergence of immunosuppressed individuals, such as patients who suffer severe abdominal surgery or who are under immunosuppressive therapy (transplants, cancer, etc), or the use of parenteral nutrition or central venous catheters (Leroy *et al.*, 2009; Puig-Asensio *et al.*, 2014).

The main fungal pathogens belong to *Candida*, *Cryptococcus* and *Aspergillus* genera, but there are many others able to cause disease with a lower prevalence. One of the main problems of these infections is the high mortality associated, which ranges between 20%–90%, depending on multiple factors, from both the pathogen and the immunological state of the patient.

The main antifungal families used to treat invasive fungal diseases are azoles, echinocandins, fluoropyrimidines and polyenes. Each family has advantages, but they also show limited activity against some fungal species (Gomez-Lopez *et al.*, 2008).

Azoles (mainly fluconazole, itraconazole, voriconazole, posaconazole and isavuconazole) inhibit ergosterol biosynthesis. It is important to highlight that fungal membranes do not contain cholesterol, but ergosterol, which is the main sterol that maintains the proper fluidity of the membrane in this kingdom. The most recent antifungal family used in clinic belongs to echinocandins (caspofungin, micafungin and anidulafungin). They inhibit the synthesis of an important component of the fungal cell wall, β -1,3-glucan, weakening the integrity of this structure. Fluoropyrimidines (5-fluorocytosine, also known as flucytosine) inhibit DNA and RNA synthesis. But the antifungals that present the strongest fungicidal activity belong to the polyenes family, which will be the main topic of this chapter. Chemically, these compounds are polyunsaturated molecules with multiple double and triple bonds. There are several polyenes that have medical use. In particular, some of these polyenes have antifungal activity, mainly, filipin, natamycin, nystatin and amphotericin B, being this last one the compound with the strongest fungicidal activity among antifungal drugs.

Amphotericin B. An Old Drug, But Still With Many Secrets Behind

In this review, we will give a brief overview of the most relevant aspects of Amphotericin B (AmB). This molecule was found by the Squibb Institute for Medical Research from cultures of a filamentous bacteria (*Streptomyces nodosus*) isolated from the soil collected in the Orinoco River region of Venezuela (Dutcher, 1968; Cereghetti and Carreira, 2006). The compound had amphoteric properties (ability to react either as acid or base), and for this reason it was named amphotericin. Originally, two types of amphotericins, A and B, were identified for their antifungal activity. Amphotericin B showed the strongest *in vitro* efficacy, so it was the main drug to treat fungal diseases since the early 60s, until new antifungal families were introduced in clinical practice decades later.

The molecular structure of AmB was determined in the 60s. AmB is a large polyene macrolactone composed of a ring of 38 carbon atoms (Fig. 1). The structure of AmB confers both hydrophilic and hydrophobic properties. The hydrophilic region is comprised by one of the sides of the ring (carbons 3–15) that contains several hydroxyl groups. The other side of the ring (carbons 20–33) contains multiple double bonds, conferring hydrophobic properties. The macrolactone also contains a ring formed by a bond between carbons 13 and 17. Finally, Amphotericin B is glycosylated, and it contains the sugar mycosamine at carbon 19. This antifungal is water-insoluble, and its preparation requires the use of organic solvents, such as DMSO. The structure and chemical properties described above will explain the biological properties of this molecule.

Mechanisms of Action

Since its discovery, AmB has been an “enigmatic” molecule because it has taken many years to understand and characterize its mechanisms of action. Furthermore, it is still not fully known how this molecule exactly exerts all the effects that have been reported in literature. But if we want to send a clear message to the reader, that would be that AmB is a “multitask” molecule because it has several mechanisms of action. Classically, it has been postulated that the main target of this antifungal is the plasma membrane, but many other studies also support that amphotericin B can also cause intracellular damage. So far, three main mechanisms of action have been attributed to AmB, and will be described in the next sections.

Fig. 1 Chemical structure of AmB.

Pore Formation at the Membrane

Polyene compounds are known to affect the cell membrane, and the specific effect of AmB for fungi was determined when it was found that it had a greater affinity for ergosterol than for cholesterol (Kotler-Brajtburg *et al.*, 1974). The first studies that proposed the “classical mechanism of action” were performed in the 70 s and suggested that AmB formed a pore at the membrane, increasing the permeability (Marty and Finkelstein, 1975; de Kruijff *et al.*, 1974; de Kruijff and Demel, 1974). The ability to form pores is due to the chemical structure. The main model of action suggests that several molecules of AmB (4–12) form an orientated structure. The inner part (lumen) of the channel would be composed by the polyol region, staying the polyunsaturated side at the external part, interacting with sterols (1:1 ratio). The diameter of the pore depends on the concentration of AmB at the membrane, and ranges from 0.16 to 16 nm (Yang *et al.*, 2013; Kaminski, 2014). The exact mechanism by which the antifungal interacts with ergosterol remains to be fully elucidated, but the mycosamine ring plays a key role in binding to the sterol (Wilcock *et al.*, 2013).

The antifungal conformation in the membrane can be very variable. For example, it has been described that at low concentrations, AmB does not fully penetrate the membrane, but stays perpendicularly to the phospholipids, in a flat position on the surface (Mouri *et al.*, 2008). At higher concentrations it can penetrate between the phospholipids and forms aggregates as macrocomplexes forming pores. Furthermore, when AmB molecules assemble to form pores, they can arrange into different conformations (Cohen, 1998, 2010). One of them is called the non-aqueous conformation, in which the AmB molecules adopt a V-shape, and only allow the movement of monovalent cations (K^+ or Na^+). On the other hand, AmB can also associate and form a channel in an open conformation (aqueous conformation), in which the antifungal molecules are in a parallel position with the phospholipids. The main factor that determines the formation of aqueous or non-aqueous pores is the ergosterol concentration, being the non-aqueous conformation formed in the absence of ergosterol. The aqueous type channels allow the diffusion of solutes such as monosaccharides. In addition, the aqueous channels can be formed in two different ways: as double barrel or single barrel. In the double barrel state, two AmB molecules interact longitudinally, acquiring a parallel orientation with the phospholipids of the membrane. When the AmB molecules associate to form pores, two barrels are formed. The COOH group of each AmB molecule is at the edge of the membrane and the OH group at carbon 35 is at the inner part, interacting with the other AmB molecule. In the single barrel model, AmB molecules do not interact longitudinally with any other, producing a single pore which causes a thinning of the membrane (Fig. 2).

In conclusion, the general idea that AmB forms pores is very simplistic as this molecules can adopt different conformations with different properties, which highlights the complexity of the effects of AmB at the membrane.

Ergosterol Sequestration

During decades, it has been believed that the mechanism of action of AmB was based on its ability to form pores and increase membrane permeability. However, later studies have demonstrated that this process is not the only one involved in the fungicidal effect of AmB. One of the alternative mechanisms proposes that AmB produces killing through binding to ergosterol without pore formation. Evidence of this alternative model was provided by the characterization of the effects of the polyene natamycin on yeasts, where it was found that this compound strongly bound to ergosterol and inhibited growth of *S. cerevisiae* without altering

Fig. 2 Different conformations of AmB in the plasma membrane. (1) Non-aqueous conformation, in V-shape, that allows the pass of small cations and is ergosterol-independent. (2) Aqueous conformation in the double barrel state, which allows the pass of small solutes, cations and anions. (3) Aqueous conformation in the single barrel state. (4) Sponge model, in which AmB does not arrange in pores, but forms aggregates at the surface that sequester ergosterol from the phospholipids, causing a disorganization of the membrane.

the plasma membrane permeability (te Welscher *et al.*, 2008). Further evidence is derived from the characterization of the role of the different regions of the molecule in pore formation and binding to ergosterol. Channel formation largely depends on the carboxylic group (C16) and on the hydroxyl at C35, and modifications of these groups still result in active amphotericin molecules (Carmody *et al.*, 2005; Szpilman *et al.*, 2008a,b; Palacios *et al.*, 2007). In this sense, it has been shown that binding of AmB to ergosterol is enough to kill the fungal cells (Gray *et al.*, 2012), and this antifungal can accumulate, forming large aggregates acting like “sponges” that extract ergosterol from the membrane (Anderson *et al.*, 2014). In this way, AmB would interfere with many of the functions that ergosterol has in the cell (cell fluidity, endocytosis, and vacuole fusion, among others) and lead to cell death. These models are also supported by the fact that alterations of the mycosamine group, required for ergosterol binding, result in a lack of fungicidal activity (Croatt and Carreira, 2011; Wilcock *et al.*, 2013).

In summary, the effects of AmB on the fungal membrane have been largely demonstrated due to its affinity to ergosterol. The mechanisms described so far (pore formation and the sponge model) are not exclusive, and there is strong evidence to believe that both take place simultaneously. Although several authors conclude that the role of pores might not be the relevant one, the fact that AmB has several effects on the membrane explains the strong fungicidal action of this antifungal.

Beyond the Membrane: Oxidative Burst and Intracellular Damage

In the previous sections, we have briefly described the effects that AmB has on the fungal membrane due to its affinity to ergosterol, but AmB has additional mechanisms of action beyond the plasma membrane. Several studies have dissociated the fungicidal effect from the increased permeability of the membrane induced by AmB (Chen *et al.*, 1978). In addition to the “sponge” model described above, many studies demonstrate that AmB can induce accumulation of reactive oxygen species (ROS) in the cell (Sokol-Anderson *et al.*, 1986; Belenky *et al.*, 2013; Mesa-Arango *et al.*, 2014; Sangalli-Leite *et al.*, 2011; Phillips *et al.*, 2003). These molecules are important regulators of multiple cellular processes, but when their concentration increase, they can alter the chemical structure of proteins, lipids and nucleic acids, causing important damage to the cells. In this way, AmB causes damage not only at the membrane, but also at multiple cellular levels.

The role of free radicals seems to be more important than the effects at the plasma membrane. For example, AmB has reduced antifungal activity under hypoxic conditions (Gale *et al.*, 1977), a fact that cannot be related to channel formation at the membrane. On the other hand, many studies indicate that induction of oxidative damage is one of the main killing mechanisms induced by AmB. It has been demonstrated that AmB has the same effects on some molecules (i.e., lipid peroxidation and protein carbonylation) as those induced by ROS (Blum *et al.*, 2008; Mesa-Arango *et al.*, 2014). Moreover, antioxidants protect the cells from killing produced by this antifungal (Sokol-Anderson *et al.*, 1988).

The mechanism by which AmB induces oxidative stress is not known. ROS are secondary subproducts of mitochondrial respiration, and it has been shown that this organelle, along with the respiration process, play a role in AmB-induced oxidative stress (Mesa-Arango *et al.*, 2014).

Another strong evidence of the role of ROS in AmB mechanism of action has been shown from the study of the filamentous fungus *Aspergillus terreus*. This mold has reduced susceptibility to this antifungal compared to other *Aspergillus* species such as *A. fumigatus*, despite both fungal species have similar ergosterol content at their membranes. In the case of this fungus, several chapters have associated its increased resistance to an increase in the response to oxidative stress, based in antioxidant enzymes such as superoxide dismutase (SOD) and catalase (Jukic *et al.*, 2017; Blum *et al.*, 2008).

Spectrum of Action and Resistance

As stated above, AmB is the antifungal that has more deleterious effects on the fungal cells including membrane, proteins, lipids and DNA, and for this reason, it is the most potent licensed antifungal available. Fungal resistance to AmB is very rare. There are very few yeast species with reduced susceptibility (i.e., some *Trichosporon* spp). However, resistance to AmB is more frequent among filamentous fungi, such as *A. terreus*, *Lomentospora prolificans*, and some *Fusarium* spp.

Secondary resistance to AmB is extremely rare, as it is required that the cells acquire simultaneously several mechanisms to resist all the challenges induced by AmB. The main known mechanism of resistance is a reduction in the ergosterol level, which has been reported in some *Aspergillus*, *Candida* and *Cryptococcus* spp (Kim and Kwon-Chung, 1974; Woods *et al.*, 1974; Safe *et al.*, 1977; Drutz and Lehrer, 1978; Vandeputte *et al.*, 2007; Currie *et al.*, 1995; Kelly *et al.*, 1994; Hitchcock *et al.*, 1987; Sanglard *et al.*, 2003). This is normally achieved by mutations in the *ERG* genes, required for ergosterol biosynthesis. However, in other cases, AmB resistance does not correlate with a decrease in ergosterol at the membrane, as is the case with *A. terreus* described above (Dannaoui *et al.*, 2000), although this has also been described in other species (Joseph-Horne *et al.*, 1996). In this sense, AmB resistance can occur when there is an inhibition of the oxidative burst, which can be due to a decreased production of ROS or an increase of detoxifying mechanisms. Since ROS are mainly produced in the cell at the mitochondria, several processes that affect its function influence the susceptibility to this antifungal. For example, strains with diminished respiration rate are less susceptible to AmB (Geraghty and Kavanagh, 2003; Mesa-Arango *et al.*, 2014). In addition, inhibition of fungal respiration with rotenone, an inhibitor of respiratory complex I (NADH dehydrogenase), produces resistance to AmB (Mesa-Arango *et al.*, 2014). In agreement, similar results have been found when there is an increase in enzymes that detoxify ROS such as superoxide dismutase or catalase (Gonzalez-Parraga *et al.*, 2011; Sokol-Anderson *et al.*, 1988; Mesa-Arango *et al.*, 2014; Guirao-Abad *et al.*, 2020; Linares *et al.*, 2013). This data is supported by works that demonstrate that yeast cells respond in the presence of AmB with the activation of signaling pathways involved in adaptation to stress, such as the MAPK Hog1 route (Mesa-Arango *et al.*, 2014; Guirao-Abad *et al.*, 2020).

Characterization of some *Candida* AmB resistant isolates has shown that, in fact, there is accumulation of several of the mechanisms described above in the same strain: mutations in *ERG* genes, decreased respiration rates and increase in ROS detoxifying enzymes (Vincent *et al.*, 2013; Mesa-Arango *et al.*, 2014). If resistance to AmB requires the accumulation of several mutations, this might explain the low incidence of secondary resistance to this antifungal. But there is another aspect that may contribute to the low resistance rate to AmB. In addition to the low probability that several mutations that confer resistance occur in the same strain, it is important to consider that virulence depends on the ability of the fungi to grow and replicate *in vivo*. In this sense, some of the mutations that confer resistance to AmB, such as those that reduce the ergosterol concentration or the respiratory rate, affect also to the replication of the yeasts. This produces a reduction of the fitness of the cells, and since the ability of these mutants to replicate *in vivo* is compromised, it is also more unlikely that they cause disease compared to WT susceptible strains (Vincent *et al.*, 2013).

Amphotericin B Toxicity and Lipidic Formulations

Although AmB is the most effective antifungal, its clinical use is limited by its toxicity and secondary effects (see detailed reviews in (Laniado-Laborin and Cabrales-Vargas, 2009; Loo *et al.*, 2013)). As AmB shows low affinity to other sterols, such as cholesterol, it can cause deleterious effects also in mammalian cells. The main toxic effect induced by AmB occurs in the kidneys. Nephrotoxicity might occur during the first two weeks of treatment, and this effect correlates with an increased mortality of the patients. There are several mechanisms by which AmB induces nephrotoxicity, including a direct effect on the function of renal tubules and renal vasoconstriction. In addition, AmB can bind to some immune receptors (i.e., TLR) and in this way, it also behaves as an immunomodulator, and alters the release of pro- and anti-inflammatory cytokines (Ben-Ami *et al.*, 2008; Mesa-Arango *et al.*, 2012). As a consequence, there are multiple side effects, such as chills, fever, hypotension, headaches, tachycardia, nausea and vomiting. Finally, it has been described that in a number of patients, AmB can inhibit erythropoiesis and reduce the number of platelets, inducing anemia and thrombocytopenia (Yeo *et al.*, 2006; Mahmud *et al.*, 2009; Kulpa *et al.*, 1981; Chan *et al.*, 1982).

The first licensed AmB in 1959 was a presentation with sodium deoxycholate (Fungizone), which is the most toxic formulation. Years later, lipidic formulations have been developed to reduce the toxic effects of AmB (Adler-Moore and Proffitt, 2008; Dupont, 2002; Torrado *et al.*, 2008; Hamill, 2013). So far, there are three different types of formulations: AmB lipidic complex (Abelcet), AmB colloidal dispersion (Amphotec) and liposomal Amphotericin B (AmBisome). Compared with the deoxycholate formulation, these formulations have significantly reduced toxicity and increased efficacy, being the liposomal AmB form the one showing the lowest nephrotoxicity. However, its high price limits its wide use in developing areas, where the incidence of some invasive fungal diseases, such as cryptococcosis, is of a great concern.

Clinical Uses of AmB

AmB has been the main choice for the treatment of invasive fungal diseases, and it shows activity against most of the pathogenic fungal species, such as *Candida*, *Cryptococcus*, *Histoplasma*, *Paracoccidioides*, *Coccidioides*, most *Aspergillus* spp (except *A. terreus*), *Mucorales* and *Fusarium*. Despite this, the new antifungal families (triazoles and echinocandins) have displaced the use of polyenes due to their toxicity or the price of the lipidic and liposomal formulations. For example, echinocandins have become the first choice to treat invasive candidiasis, and voriconazole is used for invasive aspergillosis. Still, AmB remains the first choice to treat some fungal diseases such as cryptococcosis. It is also used as secondary therapy in cases in which there is failure in the treatment with some of the first choice antifungals. This is the case for azole-resistant *A. fumigatus* or echinocandin-resistant *C. glabrata*, which is a species with intrinsic diminished susceptibility to azoles. Another example is the emerging pathogen *C. auris*, which is intrinsically resistant to fluconazole and has a particular ability to adapt to echinocandins, being in this case AmB one of the main therapeutic alternatives.

One of the main limitations for the use of AmB is its administration route. Although many attempts to develop oral formulations have been done (Cuddihy *et al.*, 2019), these have been so far unsuccessful because it is poorly absorbed from the gastrointestinal tract. For this reason, AmB formulations are injected through parenteral administration directly into the blood, and their concentration and distribution depends on the formulation administered (Loo *et al.*, 2013). It strongly binds to plasma proteins, and it has a poor diffusion to some body regions, such as the cerebrospinal fluid, aqueous humor, bile and amniotic and pericardial fluids. Finally, AmB is slowly eliminated by the body having an elimination half time above 7 days.

Conclusions

Amphotericin B was the first antifungal isolated and used in clinical practice, and paradoxically, after 60 years of use, we still do not fully understand how it kills the fungal cells. Many studies have demonstrated that AmB is a multifaceted molecule that has several mechanisms of action: pore formation, ergosterol sequestration and induction of oxidative burst. For decades, the only role attributed to this molecule was an increase in plasma membrane permeability due to channel formation, but in the last years, there are strong evidences supporting that ergosterol sequestration and induction of reactive oxygen species are the main mechanisms of action. More research is still needed to fully understand all the effects of AmB on the cells. The main limitation for its wide use is the associated toxicity. Since this antifungal exerts the strongest fungicidal activity compared to the other families, it is also important to design future strategies that will help to reduce its toxicity and, in this way, improve the efficacy and outcome of the patients.

Glossary

Antifungal susceptibility testing These methods allowed to study how susceptible/resistant is a fungal species particular isolate to the tested antifungal agents.

Aspergillosis The set of diseases caused by *Aspergillus* spp. which comprises a variety of clinical manifestations.

***Aspergillus* spp.** The most frequent genus of filamentous moulds isolated in clinical samples, causing a wide range of infections.

Azole drugs Heterocyclic compounds that contains a ring with nitrogen substitutions. In the case of triazoles, the ring contains three nitrogen atoms. In the case of moulds, triazoles are currently the antifungal drug class more commonly used to treat these infections.

Azole resistance The set of intrinsic features or subsequent alterations that enables fungi to survive in presence of azole drugs.

Broth microdilution plates A method used to test the susceptibility of a microorganism to some compounds where the drug is diluted in broth in a microtiter plate.

***Candida* spp.** A major human yeast pathogen that causes both mucosal and deep tissue infections.

Candidiasis The set of diseases caused by the different *Candida* species, including a variety of clinical manifestations.

Cyp51A/Erg11p Cytochrome P450 14- α demethylase enzyme, the target of azole drugs.

Demethylation inhibitors A drug family that inhibits a key enzyme involved in ergosterol biosynthesis, the 14- α sterol demethylase, impairing the fungal growth. Imidazoles and triazoles are the most used compounds of this family.

Efflux pumps Proteins that selectively admit or excludes chemicals so that they can regulate intracellular concentration of different compounds.

Ergosterol Main sterol in membranes of fungal cells.

Fungicides Chemical compounds used mainly in agriculture to kill moulds and their spores in crops.

Invasive fungal diseases An infection caused by fungal species characterizes by the invasion of a tissue, usually due to the lack of an effective immune response.

Minimum inhibitory concentration The lowest concentration of a compound which does not enable growth of a specific microorganism.

Multi-azole resistance A set of characteristics that enables fungi to survive in presence of several azole drugs.

Point mutation Is a type of changes in the DNA sequence in which one single nucleotide base is added, deleted or substituted for another nucleotide.

Transcription factors Transcription factors include a wide number of proteins that initiate and regulate the transcription of genes.

Introduction

Invasive fungal diseases (IFD) are life-threatening infections and the main cause of mortality and morbidity in immunocompromised patients or in high risk patients who suffer from immunodeficiencies, hematological malignancies, solid organ transplant recipients, or those with chronic obstructive pulmonary disease or receiving high-dose and continued corticosteroid therapy (Low and Rotstein, 2011; Akan *et al.*, 2013; Rüping *et al.*, 2008; Walsh and Gamaletsou, 2013).

The most common fungal pathogens involved in invasive diseases are *Candida albicans* and *Aspergillus fumigatus* (Schwartz and Patterson, 2018; Pagano *et al.*, 2011). However, other *Candida* non-*albicans* species as well as other filamentous fungi, have been increasingly reported and quite often causing disseminated infections in immunocompromised hosts (Alcazar-Fuoli and Mellado, 2014; Picazo *et al.*, 2008; Friedman and Schwartz, 2019).

In spite of the improvements in diagnosis, and antifungal therapy for treating and preventing fungal infections, morbidity and mortality rates associated with these infections remains very high (Neofytos *et al.*, 2009). The most important factors are associated with the status of the host; however, other aspects can also have a major impact. Among them, fungal diagnosis is not straightforward and therefore antifungal therapy is often initiated too late. The key issue for a successful recovery is the prompt treatment with the appropriate drug, avoiding, when possible, drug toxicity (Badiie and Hashemizadeh, 2014; Pianalto and Alspaugh, 2016; Wiederhold, 2017).

This situation becomes more complicated because emerging resistance to existing antifungals is a current problem (Garcia-Rubio *et al.*, 2017; Pristov and Ghannoum, 2019) and a poor response to antifungals has been described in clinical isolates (Pfaller, 2012; Schwartz and Patterson, 2018).

However, some new molecular tools can provide a valuable amount of novel information that eventually might be applied to improve patient management. The most remarkable one is whole genome sequencing (WGS) which has emerged as a useful tool

for the analysis of genetic differences between fungal isolates, their genetic background, and even to know how antifungal resistance was developed (Garcia-Rubio *et al.*, 2018).

Antifungals in Clinical Use

The current antifungal drugs target a limited number of cellular processes. Most of them interfere with the ergosterol biosynthesis, which is the main sterol in fungal membranes. The need for new antifungal agents is undeniable since current therapeutic choices to treat IFD are limited to three major classes: polyenes, echinocandins and azole drugs (Patterson, 2005; Campoy and Adrio, 2017).

Amphotericin B (AMB) is included in the polyene group of drugs, and it has been the standard treatment for invasive fungal infections during decades. Ergosterol is the target of this compound, but due to the high toxicity to the host, probably owing to the interaction with cholesterol host-cell membranes, its use has been compromised and is no longer administrated as first choice treatment (Ostrosky-Zeichner *et al.*, 2003).

The use of echinocandins-caspofungin (CSF), micafungin (MCF) and anidulafungin (ANF)- has significantly improved the outcome of patients with these infections (Patil and Majumdar, 2017) as they have favorable safety profiles and a broad spectrum of activity. Their effectiveness is based on the blockage of cell-wall synthesis by inhibiting β -(1,3)-D-glucan synthase (Turner *et al.*, 2006). They are the primary treatment for invasive infections caused by most of *Candida* species (Bennett, 2006; Wiederhold, 2016) and are only effective in combination with azoles for treating *Aspergillus* spp. infections (Perlin, 2007; Panackal, 2016).

Azole drugs include fluconazole (FCZ), itraconazole (ITZ), voriconazole (VRZ), posaconazole (PSZ), and isavuconazole (ISZ). The last of them has been recently introduced in clinical use as a new extended-spectrum triazole, and its activity against *Aspergillus* has been proved (Miceli and Kauffman, 2015). All of them are well tolerated and are active against diverse fungi (Andes and Dismukes, 2011). Besides, triazoles are orally available, which makes them essential for long-term therapy. FCZ is well established as a leading drug in the setting of prevention and treatment of mucosal and invasive candidiasis (Charlier *et al.*, 2006). Although VRZ is recommended as first-line therapy for invasive aspergillosis (IA), ITZ is still commonly used for chronic and allergic non-invasive forms of aspergillosis, while PSZ was shown to reduce the number of invasive fungal infections in neutropenic patients (Patterson, 2005).

The emergence of antifungal resistance is a current problem that could be influenced by the widespread use of these compounds, especially azoles, as antifungal agents both in the clinical and the agricultural setting (van der Linden *et al.*, 2011; Pfaller, 2012; Manavathu *et al.*, 1998).

Drug resistance among fungi species represents the primary cause of treatment failure in patients with invasive fungal infections and an important and alarming health problem, since once the resistance is acquired to a compound, it could lead to cross-resistance to other drugs of the same family (Sanglard, 2016).

This manuscript reviews the current understanding of azole drug resistance with special emphasis on the molecular resistance mechanisms that have been described mainly in *Candida* and *Aspergillus* spp.

Definition of Resistance

Resistance to antifungal drugs could be defined as the set of intrinsic features or alterations that enables fungi to survive in presence of these substances.

Generally, resistance can be classified as either microbiological or clinical. Microbiological resistance depends directly on the microorganism and can be classified as primary or intrinsic, when an organism is resistant to a drug prior to exposure, and secondary or acquired resistance, which is developed in response to the exposure against an antifungal agent. Clinical resistance has an impact on treatment failure despite of its susceptibility *in vitro*. This may happen when the drug used is not able to reach the infected site in enough concentration or/and the host immune response is not able to eradicate the fungi (Kanafani and Perfect, 2008). Also pharmacokinetic and pharmacodynamics parameters of the drug have an important role (Nucci and Perfect, 2008).

How Resistance is Determined? Antifungal Susceptibility Testing

Antifungal susceptibility testing (AST) refers to the ability of a specific organism to grow *in vitro* in the presence of a particular drug. The standardization of a methodology, which allows reproducible and reliable results, has been thoroughly explored. Accordingly, Clinical and Laboratory Standards Institute (CLSI) and the European Committee on Antibiotic Susceptibility Testing (EUCAST) have published guidelines for testing *Candida* and *Aspergillus* isolates using standardized broth microdilution methods (Arendrup *et al.*, 2012; Clinical Laboratory Standards Institute, 2008a,b; Subcommittee on Antifungal Susceptibility Testing of the ESCMID European Committee for Antimicrobial Susceptibility Testing, 2008; Pfaller *et al.*, 2009; Verweij *et al.*, 2009). These methodologies allow the *in vitro* establishment of antifungal cut-off as well as the identification of resistant isolates that is crucial to choose the most suitable treatment.

The AST reference methods are based in broth microdilution plates that can easily be prepared and frozen in the clinical laboratory until susceptibility testing is performed. In general, the incubation period is usually 24–48 h, and after that the minimum inhibitory concentration (MICs) are read. However, the difference between MICs reading at 24 and 48 h is minimal for some isolates, and does not alter the interpretative category (Alastruey-Izquierdo *et al.*, 2015). For visual interpretations the end point for azoles is the point presenting substantial reduction in growth and could also be referred to as 80% reduction in growth when compared with growth control. However, when the microdilution method is used and read by spectrophotometer absorbance, 50% of growth inhibition is the value that best approximates the visual endpoint (Rex *et al.*, 2001).

Both procedures, CLSI and EUCAST, have been extensively employed and it has been demonstrated that are able to characterize the mould susceptibility through MICs to antifungal drugs (Alastruey-Izquierdo *et al.*, 2015). However, breakpoints to allow discrimination between susceptible and resistant strains *in vivo* have not been established for all species (Johnson, 2008). Therefore, *in vivo* correlation studies are urgently needed to develop interpretative MIC clinical breakpoints (CBPs) for the different antifungals used for treating these infections.

Azoles: Mode of Action

The use of mould active azoles caused a revolution in medical mycology due to their broad spectrum and their reduced toxicity compared to amphotericin B and has clearly improved patient survival (Sheehan *et al.*, 1999; Neofytos *et al.*, 2009).

The chemical families that inhibit C-14 demethylation are imidazoles, which are mostly used topically, and triazole drugs. They are classified chemically based on the number of nitrogen atoms in the azole ring (two for imidazoles and three for triazoles) (Andes and Dismukes, 2011). Collectively, these compounds are called sterol demethylation inhibitors (DMIs) and are widely used in both the clinical (as treatment or prophylaxis choice for fungal infections) and in the environmental setting (as fungicides in agriculture) (Kelly *et al.*, 1995; Hollomon, 2017).

In the mammalian cells, cholesterol is one of the most important sterols present in the cell membrane. However, the major sterol in the fungal cell is a different one, the ergosterol, which makes it a suitable antifungal target. The triazoles target fungal cell growth by inhibiting a key enzyme involved in ergosterol biosynthesis, the 14- α sterol demethylase of the cytochrome P450s Cyp51 family, that are encoded by *ERG11* in yeast and *cyp51* gene in moulds. This enzyme removes the methyl group at position C-14 of precursor sterols. The inhibition of the ergosterol synthesis at that level produces the accumulation of toxic sterols, such as lanosterol or eburicol, which substitute the methylated sterols and deplete ergosterol from fungal membrane, leading to cell membrane instability, growth impairment, and subsequent cell death (Kelly *et al.*, 1995; van den Bossche *et al.*, 1995; Waterman and Lepesheva, 2005; Parker *et al.*, 2014) (Fig. 1).

Differential antifungal potency between azoles is due to changes in their affinity for the enzyme and their different toxicity and drug interaction profiles depend on the cross-inhibition of various human cytochrome P450 enzymes (Lat and Thompson, 2011).

Since the first azole compounds were synthesized (imidazoles, such as miconazole, clotrimazole, and ketoconazole) some chemical modifications have been made in order to increase their activity and reduce cell toxicity, giving rise to the triazoles (Campestre *et al.*, 2017). Five triazole compounds (fluconazole, itraconazole, voriconazole, posaconazole, and isavuconazole) have been clinically approved and are currently widely used for the prevention and treatment of several life-threatening fungal infections (EMA, 2012a,b). Fluconazole (FCZ) is fungicidal in most species of *Candida* and was considered first-line agent in the past, however clinical trials have demonstrated that echinocandins can improve rate of survival (Tagliaferri and Menichetti, 2015). With regard to filamentous moulds, FCZ have no clinical relevant activity. *Aspergillus* spp. are intrinsically resistant to FCZ (Leonardelli *et al.*, 2016), unlike ITZ, VCZ, and PSZ which have been shown to have good *in vitro* and *in vivo* activity against these fungi. However, ITZ and VRZ are only fungistatic against *Candida* species (Greer, 2003). At present, VCZ is the most common antifungal compound used for invasive aspergillosis (IA). Isavuconazole (ISZ), approved for IA treatment in 2015 (Seyedmousavi

Fig. 1 (A) Normal ergosterol biosynthesis pathway resulting in cell growth (B) Ergosterol biosynthesis via the inhibition of Erg11/Cyp51 produces the accumulation of toxic sterols and subsequent cell death.

et al., 2015), has a broad spectrum of *in vitro* activity and *in vivo* efficacy against a wide range of yeasts and moulds including *Aspergillus* spp., and *Candida* spp. (Perkhofer *et al.*, 2009; Guinea *et al.*, 2008; Espinel-Ingroff *et al.*, 2013; Howard *et al.*, 2013).

Other newer triazole compounds are still under investigation (Turel, 2011). For instance, albaconazole (ABZ) has shown *in vitro* activities against pathogenic yeasts, and filamentous fungi and has been proven effective in some animal models (Miller *et al.*, 2004; Bartoli and Uriach, 2005).

Azole Drug Resistance Mechanisms

The resistance mechanisms to antifungal agents can differ between groups of drugs mainly due to the mode of action of each class of antifungal compound. As mentioned before for antifungal drugs in general, also two types of resistance have been described within azoles, the primary or intrinsic resistance and the secondary resistance (Anderson, 2005; Andes and Dismukes, 2011; Cowen *et al.*, 2015). The first results from the natural interaction between the fungal species and the azole compounds and occurs regardless of previous azole exposure (White *et al.*, 1998). In addition, fungal azole resistance can be explained by acquired secondary resistance mechanisms, which have been studied at molecular level and will be extensively explained here. The development of this type of resistance can evolve by the selection of the most resistance species in the host or by enabling the emergence of a resistant clone within a fungal species (Verweij *et al.*, 2016). Clinically, the main problem of secondary resistance is the selection of these resistant organisms during the azole treatment (Andes and Dismukes, 2011), and consequently, the restriction of treatment options (Rodriguez-Tudela *et al.*, 2008a). Therefore, a better understanding of mechanisms that underlie azole resistance is critical in order to avoid and prevent resistance development (Snelders *et al.*, 2008).

Azole resistance can develop through multiple mechanisms including: (1) target alteration or (2) its overexpression, (3) up-regulation of multidrug transporters, (4) transcription factors that play a role in cellular changes conferring tolerance to drug stress or toxicity or, (5) through biofilm sequestration.

Azole Resistance Mechanisms in *Candida* Spp.

The extensively use of FCZ and other triazoles due to their effectiveness against this genus, as prophylaxis, empirical therapy or diagnostic-driven therapy, has caused a selective pressure which has led to the emergence of less susceptible species and secondary resistance among primarily sensitive isolates (Cowen *et al.*, 2015).

Azole resistance in *Candida* spp. has been widely reported and well-studied. There are several mechanisms that can lead to acquired azole resistance in species of *Candida* genus (Fig. 2). The most commonly reported resistance mechanism is the decrease in the intracellular azole concentration by the activity of some efflux pumps (Fig. 2.1), encoded by the ATP-binding cassette (ABC) transporters or by the major facilitator superfamily genes (MFS) (Kanafani and Perfect, 2008; Sanglard, 2016). Induction of *Candida* drug resistance by increased expression of CDR genes, which encode efflux pumps, tends to reduce the accumulation of all azole drugs and it is often sufficient for antifungal resistance in certain species; i.e., CDR1 and CDR2 genes in *Candida albicans* and CgCDR1, CgCDR2 and CgSNQ2 genes in *Candida glabrata*. Conversely, efflux pumps encoded by multidrug resistance (MDR) genes are usually selective for fluconazole (Pfaller, 2012) and are restricted to MDR1 from *C. albicans* (Sanglard *et al.*, 1995; Calabrese *et al.*, 2000) and *Candida dubliniensis* (CdMDR1 and CdCDR2) (Moran *et al.*, 1998).

The upregulation of ABC and MFS transporters is controlled by different transcription factors (TFs) (Fig. 2.2). In *C. albicans*, CDR1 and CDR2 are regulated by TAC1 (Coste *et al.*, 2004), and also CDR1 by another regulator called MRR1 (Morschhäuser *et al.*, 2007). In *C. glabrata*, CgPdr1 is a transcriptional factor involved in azole resistance via upregulation of ABC genes including, at least, CgCDR1, CgCDR2 and CgSNQ2 (Ferrari *et al.*, 2009; Vermitsky *et al.*, 2006).

Another resistance mechanism consists in increasing the number of drug targets (Fig. 2.3), so a higher azole concentration is needed to saturate all target molecules, leading to azole resistance. In *C. albicans*, the overexpression of the target gene (*ERG11*) mediated by the transcription factor UPC2 (Fig. 2.3) has been associated with azole resistance (Dunkel *et al.*, 2008; Lohberger *et al.*, 2014).

Finally, acquisition of point mutations in the azole target *ERG11* (Fig. 2.4), which encodes the enzyme 14 α -lanosterol demethylase in *Candida* spp., results in amino acid substitutions that decrease the affinity of the target (Erg11p) for azoles (Lamb *et al.*, 2000). Several mutations Erg11p have been described but only a few of them have been directly related to azole resistance (Morio *et al.*, 2010). For example, Y132F/H and G464S/D have been shown to confer azole resistance in *C. albicans*, *C. dubliniensis* and *Candida tropicalis* (Perea *et al.*, 2001; Chau *et al.*, 2004; Kelly *et al.*, 1999; Forastiero *et al.*, 2013; Vandeputte *et al.*, 2005). Recently, combined mutations in both, *ERG11* and another enzyme of the ergosterol biosynthesis pathway encoding a C-5 sterol desaturase (*ERG3*) seem to be an emerging azole resistance mechanism in *C. albicans* and *C. tropicalis* (Morio *et al.*, 2012; Forastiero *et al.*, 2013; Eddouzi *et al.*, 2013; Jiang *et al.*, 2013; Martel *et al.*, 2010). However, the innate fluconazole resistance phenotype of *Candida krusei* seems to be due to the low sensitivity of the azole target (Erg11p) to azole drugs in combination with the constitutive expression of the multidrug efflux pump Abc1p (Lamping *et al.*, 2009). Only one study has addressed the molecular mechanisms underlying azole resistance in *C. parapsilosis*, concluding that similarly to *C. albicans*, its tolerance to azoles involves the activation of efflux pumps and/or their increased expression (Figs. 2.1 and 2.3) (Silva *et al.*, 2011).

Much less is known in the development of extra or intracellular compartments to sequester azoles. *Candida* spp. is able to form biofilm in some specific growth conditions (Ramage *et al.*, 2005; Desai and Mitchell, 2015). Biofilm formation has also been recognised

Fig. 2 Schematic representation of the main azole resistance mechanism in *Candida* spp.

as a potential factor for fungal drug resistance due to the production of an exopolymetric material that inhibits or restricts penetration of antifungal drugs (Taff *et al.*, 2013). This process has been clearly documented in *C. albicans* azole resistance (Mitchell *et al.*, 2015; Bonhomme and d'Enfert, 2013) and also has been described in *Candida auris* (Kean *et al.*, 2018). In relation to *C. auris*, one of the most troubling changes in the epidemiology of invasive candidiasis (Rhodes and Fisher, 2019), it is worth mentioning its rapidly worldwide emergence and its potential for efficient nosocomial transmission (Friedman and Schwartz, 2019; Kordalewska and Perlin, 2019). It is generally accepted that most isolates are multi-drug resistant (Arendrup *et al.*, 2017). Thus, some Erg11p specific mutations strongly associated with azole resistance have already been described (Chow *et al.*, 2018; Lockhart *et al.*, 2017; Rhodes *et al.*, 2018).

Azole Resistance Mechanisms in *Aspergillus* Spp.

The genus *Aspergillus* comprises 344 species (Samson *et al.*, 2014) and many of them have been described as pathogenic in humans and animals (Sugui *et al.*, 2014). In *A. fumigatus* in particular, azole resistance is well studied due to its clinical importance since it is the predominant etiological agent isolated from immune-compromised patients (Segal, 2009; Vermeulen *et al.*, 2015). Azoles are the main antifungal drugs that are used both in agriculture as well as in the clinical setting. However, the existing selective pressure in the environment and in the patients generates different azole resistance mechanisms (Bueid *et al.*, 2010; Snelders *et al.*, 2008; Camps *et al.*, 2012a) (Fig. 3). As a consequence, there may be found different azole susceptibility patterns based on their resistance mechanism, with increasing MICs to one, two, or all triazoles (Rivero-Menendez *et al.*, 2016; Garcia-Rubio *et al.*, 2017).

Therefore, different azole resistance profiles can be mainly attributed to specific amino acid changes in Cyp51A protein, which are caused by single-point mutations in the azole target gene, *cyp51A* encoding a 14- α sterol demethylase (Figs. 3.1 and 4).

The main triazole resistance mechanisms most commonly described when the acquired resistance is generated during extended periods of azole treatment involves the following amino acid substitutions:

A mutation in position glycine 54 (G54) can result in amino acids changes such as G54E, G54V, G54R and G54W. Clinical strains with these mutations show resistance with high MICs to ITZ and also to PSZ but not to VRC (Diaz-Guerra *et al.*, 2003; Nascimento *et al.*, 2003; Mann *et al.*, 2003).

Another important mutation is located at methionine 220 (M220), which can change to M220V, M220K, M220T and M220I. This mutation leads to ITZ resistance and reduced susceptibility to PSZ, and VRZ (Mellado *et al.*, 2004; Chen *et al.*, 2005).

Apart from these there are other single point mutations that should be mentioned. The point mutation G448S (Bellete *et al.*, 2010; Pelaez *et al.*, 2012; Krishnan Natesan *et al.*, 2012) confers resistance to VRZ and moderate ITZ and PSZ resistance while the

Fig. 3 Schematic representation of the main azole resistance mechanism in *Aspergillus* spp.

Fig. 4 Schematic representation of the *A. fumigatus* main azole resistance mechanisms involving promoter and *cyp51A* gene modifications and their corresponding azole susceptibility profiles.

G138C substitution has been described in a multiazole resistant strain reported from patients under azole treatment (Howard *et al.*, 2006; Albarrag *et al.*, 2011). The last single point mutation described directly related to azole resistance was P216L (Camps *et al.*, 2012b; Hagiwara *et al.*, 2014; Dabas *et al.*, 2018).

Other single-point mutations have been associated with a reduced azole susceptibility profile or azole resistance (G138R, N22D, F165L, F219C, F219I, D262Y, A284T, Y431C, G432, G434C, T440A, N479D and Y491H) (Howard *et al.*, 2009; Mortensen *et al.*, 2011; Bueid *et al.*, 2010; Manavathu *et al.*, 2003; Howard *et al.*, 2006; da Silva Ferreira *et al.*, 2004; Alanio *et al.*, 2011; Escibano *et al.*, 2011; Bader *et al.*, 2013) but their role in azole resistance remains to be fully clarified. Also two combinations of Cyp51A amino acid substitutions (F46Y, M172V and D255E or F46Y, M172V, N248T, D255E and E427K) (Alanio *et al.*, 2012; van der Linden *et al.*, 2015; Rodriguez-Tudela *et al.*, 2008b; Howard *et al.*, 2009; Snelders *et al.*, 2009; Zhao *et al.*, 2013; Chowdhary *et al.*, 2015; Kidd *et al.*, 2015; Prigitano *et al.*, 2014; Özmerdiven *et al.*, 2015; Hurst *et al.*, 2017; Shalhoub *et al.*, 2015; Wang *et al.*, 2014) have been described among

clinical and environmental strains showing a susceptibility profile with higher azole MICs than wild-type *A. fumigatus* strains. However, some authors have claimed that these substitutions are not associated with azole resistance (Escribano *et al.*, 2011) because their azole MICs normally remained below the accepted threshold defined for resistant isolates (Verweij *et al.*, 2009), while other authors concluded that they could be associated with a poorer azole treatment response (Alanio *et al.*, 2012).

Triazole resistance in *A. fumigatus* can evolve during therapy, but resistant isolates are also being detected in azole-naïve patients, with evidence to suggest acquisition of resistant isolates from the environment. In this context, a new group of resistance mechanisms in which *cyp51A* overexpression is involved together with Cyp51A mutations has been described (Figs. 3.1 and 3.2). It has been speculated that this resistance mechanism derived from environmental origin due to extended use of demethylation inhibitors (DMIs) as agricultural fungicides.

Normally, it is caused by a particular genetic alteration that consists in tandem repeats (TR) integration of various sizes (34, 46 or 53 bp) in the *cyp51A* gene promoter and in most cases in combination with one or more point mutations in Cyp51A. All of them confer a multi-azole resistance profile. The most common tandem repeat insertion is the TR34/L98H (Mellado *et al.*, 2007) which confers pan-azole resistance. This particular mechanism conferring multi-azole resistance has been observed most frequently in clinical isolates in the Netherlands where it has also been found in the environment, suggesting a possible environmental origin of the resistance (Snelders *et al.*, 2008, 2009). The next most common mechanism is the TR46 integration in combination with two point mutations, Y121F and T289A, which mainly leads to VRZ resistance (van der Linden *et al.*, 2013).

In addition, there are some *cyp51A*-independent *A. fumigatus* azole resistance mechanisms, much less common than the ones mentioned previously. For example, the decrease in the intracellular azole concentration by active efflux systems, such as ATP-binding cassette (ABC) transporters, or the major facilitator superfamily (MFS) (Fig. 3.3) (Sanglard, 2016). Also, some transcription factors have been reported as contributing to azole resistance in *A. fumigatus* (Fig. 3.4), such as SrbA (Willger *et al.*, 2008), a transcriptional regulator belonging to the sterol regulatory element binding protein (SREBP), the transcription factor HapE (Camps *et al.*, 2012; Gsaller *et al.*, 2016) and AfYap1 which is regulated by oxidative stress (Qiao *et al.*, 2010). Finally, mutations in the mitochondrial complex I probably have a role in azole drug resistance through membrane alterations (Bromley *et al.*, 2016).

Although *A. fumigatus* azole resistance is the main concern in this field, other human pathogenic species also show azole resistance (Richardson and Lass-Flörl, 2008). Azole resistance caused by amino acid changes in Cyp51A target have been linked to *Aspergillus lentulus* (Alcazar-Fuoli *et al.*, 2011; Mellado *et al.*, 2011), another species from *Aspergillus* section *Fumigati* that shows high VCZ and ITZ MICs (Alcazar-Fuoli *et al.*, 2008; Alastruey-Izquierdo *et al.*, 2014). The same azole profile is shown by *Aspergillus viridinutans* (Lamoth, 2016). Other species within the *Fumigati* section, such as *Aspergillus fumigati*affinis and *Neosartorya pseudofischeri* (Alcazar-Fuoli *et al.*, 2008; Balajee *et al.*, 2005) have high triazoles MICs while *Neosartorya udagawae* only has high VCZ MICs (Vinh *et al.*, 2009).

Conclusions

In conclusion, the development of antifungal drug resistance is the inevitable and logical consequence of their broad use in different settings, although the frequency and clinical relevance is, at present, unknown. However, it is acknowledged that azole resistance or even fungal decreased azole susceptibility have a negatively impact on treatment response and the outcome of IFDs. Further understanding of antifungal resistance should be promoted at different levels:

- (1) The study of molecular mechanisms of antifungal drug resistance is the most valuable strategy to resistance development control and also in helping to develop safer and more active molecules able to avoid them. In the meanwhile, it is important the correct use of the available tools: epidemiological surveillance of resistance emergence and to use all the efforts towards prompt diagnosis in order to accomplish an adequate and effective treatment.
- (2) Reference microdilution methods have established the guidelines for AST. However, the standardization of additional methods, such as the E-test, colorimetric MIC determinations, and newer antifungal susceptibility methods is lacking. This could make susceptibility testing less time consuming and, eventually more accessible to hospital labs. As new antifungal agents are introduced, the AST will have to be further modified to accommodate special concerns with these drugs and an expanded spectrum of fungal pathogens.
- (3) Research on new antifungal agents as well as new combinations of antifungal drugs would be more than welcomed to avoid or to minimize resistance. Particularly, the challenges of emerging fungal pathogens underscore the need for the development of new antifungal agents and strategies.

Echinocandins

Alexander J Lepak and David R Andes, University of Wisconsin, Madison, WI, United States

Background and Structure

The naturally occurring precursors, pneumocandins, to modern-day echinocandins were originally discovered in the 1970s (Patil and Majumdar, 2017). After numerous attempts to chemically modify these precursors as safe and effective drugs, caspofungin acetate was the first developed and approved for clinical use in the United States in 2001. Currently, there are three echinocandins available for clinical use and include caspofungin, micafungin, and anidulafungin. They represent a medication class that is critically important for the prevention and treatment of invasive fungal infections, in particular invasive candidiasis, and rank second to triazoles in overall antifungal use (Toda *et al.*, 2019; Vallabhaneni *et al.*, 2018). Additional related agents are in development, including the long acting echinocandin rezafungin (formerly CD101 and SP3025), and a non-echinocandin glucan synthase inhibitor ibrexafungerp (formerly SCY-078 and MK-3118).

Each of the 4 echinocandins are large, semisynthetic structures that contain a hexacyclic lipopeptide core composed conserved amino acid residues (e.g., 3,4-dihydroxyhomotyrosine and 3-hydroxy-proline) (Balkovec *et al.*, 2014; Zambias *et al.*, 1992) (Fig. 1). Unique structural components to each echinocandin are due to side chain modifications that affect pharmacokinetic properties such as water solubility, half-life (in the case of rezafungin), and decreased toxicity compared to parent compounds. Ibrexafungerp, which targets to the same cellular process as echinocandins, is chemically and structurally different from echinocandins. Enfumafungin, an acidic terpenoid, was discovered through natural product screening and first described in 2000 (Onishi *et al.*, 2000). Ibrexafungerp is a derivative of enfumafungin developed with enhanced antifungal potency and pharmacokinetic properties (Davis *et al.*, 2019).

Mechanism of Action, Spectrum of Activity, and Susceptibility Testing

Echinocandins competitively inhibit the fungal cell wall enzyme (1 → 3)-β-D-glucan synthase, which is responsible for synthesis of an essential polysaccharide (β-1,3 glucan) necessary for cell wall integrity (Douglas *et al.*, 1997). Against yeast that contain this

Fig. 1 Echinocandin chemical structures (pubchem.gov).

critical cell wall enzyme and structure, echinocandins are cidal as they result in cell wall instability and resultant lysis. Therefore, susceptibility testing for echinocandins against yeast involves determining the minimum inhibitory concentration (MIC), defined as the drug concentration that yields no visible growth by eye. Each of the three approved echinocandins (caspofungin, micafungin and anidulafungin) demonstrate potent in vitro activity with very low MICs against *Candida* spp. including *C. albicans*, *C. glabrata*, *C. tropicalis*, *C. dubliniensis*, and *C. krusei* (Chandrasedu and Sobel, 2006; Pfaller et al., 2003; Vazquez and Sobel, 2006). Higher MICs have been demonstrated for *C. parapsilosis*, *C. lusitanae*, and *C. guilliermondii*; however, pre-clinical and clinical studies have demonstrated these agents to be useful for the treatment of infections due to these pathogens despite higher MIC values (Barchiesi et al., 2006; Fernandez-Ruiz et al., 2014; Pfaller et al., 2006, 2008).

Against *Aspergillus* spp, echinocandin effect is fungistatic as β -1,3 glucan synthesis is limited to the hyphal tips (Bowman et al., 2002). Susceptibility testing, therefore, is different for echinocandins when tested against *Aspergillus* spp., with the primary endpoint of drug effect read as the minimum effective concentration, or MEC. This is determined visually as the lowest concentration of drug that results in aberrant hyphal growth in contrast to the long, infrequently branched hyphal elements noted in controls (Kurtz et al., 1994). Finally, in addition to *Candida* and *Aspergillus* spp, echinocandins also have potent in vitro effect against the cyst form of *Pneumocystis jirovecii* (Schmatz et al., 1990).

The spectrum of activity does not include some notable fungal pathogens, including filamentous fungi other than *Aspergillus* spp (e.g., Mucorales, *Fusarium* spp, *Scedosporium/Lomentospora* spp), *Cryptococcus* spp, *Trichosporon* spp, or the endemic dimorphic fungi (Almyroutidis et al., 2007; Cuenca-Estrella et al., 1999; Diekema et al., 2003). In general, the lack of activity against these other pathogenic fungi is felt due to diminished presence or lack of β -1,3 glucan (Aguilar-Zapata et al., 2015). It should be noted, the two novel agents in development that are discussed in this review, rezafungin and ibrexafungerp, have similar effect and spectrum given they also target the fungal cell wall enzyme (1 $\rightarrow$ 3)- β -D-glucan synthase (Pfaller et al., 2013, 2017a,b, 2016; Schell et al., 2017).

Resistance to Echinocandins

Intrinsic resistance, as noted above, is due to diminished presence or lack of the target enzyme (1 $\rightarrow$ 3)- β -D-glucan synthase. For example, *Cryptococcus* spp and *Trichosporon* contain β -1,6 glucan as the predominant cell wall polysaccharide (Aguilar-Zapata et al., 2015; Kauffman and Carver, 2008). In general, acquired antimicrobial resistance can be due to drug efflux, altered drug target, altered drug penetration, or protection via enzymatic degradation or protection proteins. Multidrug-resistant (MDR) transporters, while important for resistance for other agents including triazoles, are not a significant mechanism of drug resistance for echinocandins (Niimi et al., 2006). Thus, when echinocandins were newly developed there was lack of cross-resistance in *Candida* spp that contained triazole resistance (e.g., fluconazole resistance) secondary to drug efflux (Bachmann et al., 2002; Richards et al., 2008). Nevertheless, resistance has emerged to echinocandins for *Candida* spp. leading the CDC to list drug-resistant *Candida* as a major medical threat (CDC, 2019). Echinocandin resistance is most prevalent in *C. glabrata*, with rates that vary geographically from 0% to 10% (Alexander et al., 2013; Astvad et al., 2018; Fraser et al., 2019; McCarty et al., 2018; Pfaller et al., 2019; Toda et al., 2019) and *C. auris*. Rates of resistance for *C. auris* is more difficult to accurately define as we continue to learn more about the incidence of this emerging pathogen, what clinical breakpoints should be used to adequately define resistance, and the epidemiological distribution and frequency of resistance phenotypes and genotypes (Lockhart, 2019; Lockhart et al., 2017).

Echinocandin resistance is primarily mediated through alterations in the catalytic subunits of the glucan synthase enzyme (Fksp) (Douglas, 2001, 1997; Perlin et al., 2015). Specifically, "hot-spot" areas located within the genes *FKS1* and *FKS2* have been identified along with specific mutational changes that confer echinocandin resistance (Garcia-Effron et al., 2010, 2009; Katiyar et al., 2006; Pham et al., 2014; Shields et al., 2015; Zimbeck et al., 2010). To date, there are numerous reported unique mutations that yield heterogeneous changes in echinocandin MIC. In resistance development models, it appears that *FKS1/2* mutational change is a final step in response to stress from drug exposure, but other adaptational changes, primarily driven by cell stress response pathways, to echinocandin exposure occur prior to *FKS* mutational change (Healey and Perlin, 2018). These pathways may explain the clinical phenomena of echinocandin tolerance, which is when an infection due to *Candida* spp are not responding to echinocandin therapy despite not having a genetic resistance determinant (e.g., *FKS* mutation) and previously exhibiting phenotypic susceptibility (Healey and Perlin, 2018; Perlin et al., 2017; Wiederhold et al., 2005). Clinical reports of *FKS* mutations leading to increased echinocandin MIC and subsequent poor patient outcome have increased in the past decade, most alarmingly multi-drug (triazole and echinocandin) resistant *C. glabrata* (Alexander et al., 2013; Beyda et al., 2014; Farmakiotis et al., 2014; Pfaller et al., 2012; Vallabhaneni et al., 2015). Additionally, the emergence of multi-drug resistant *C. auris* has occurred, with multiple reports indicating resistance mechanisms are similar to other *Candida* spp. and secondary to stress response pathways leading to *FKS* mutational changes in the drug target (Biagi et al., 2019; Chowdhary et al., 2018; Kordalewska et al., 2018). Reduced susceptibility to echinocandins noted in some species groups, for example *C. parapsilosis* and *C. guilliermondii*, are mediated through naturally present *Fks* amino acid substitutions in the wild-type population that render reduced susceptibility to echinocandins (Perlin et al., 2017). While the MIC may be higher in these isolates, clinically they respond well to echinocandin therapy and pre-clinical models suggest further alterations that lead to overt resistance may adversely affect fitness and stress tolerance (Papp et al., 2018).

With the discovery that *FKS* mutational changes were the primary driver for overt resistance in *Candida*, laboratory generated *FKS* mutant *A. fumigatus* strains were produced that demonstrated similar in vitro resistance to echinocandins (Gardiner et al., 2005; Rocha et al., 2007). However, clinical observation of acquired echinocandin resistance due to *FKS* in *Aspergillus* has been reported in only a single patient with chronic pulmonary aspergillosis (Jimenez-Ortigosa et al., 2017). While echinocandins are

used less frequently in invasive aspergillosis, primarily limited to salvage or combination use, it is striking how infrequent this has been observed for this pathogen and warrants further investigation.

Resistance to both rezafungin and ibrexafungerp has been demonstrated in vitro and amongst select clinical isolates in surveillance programs. Not surprisingly, rezafungin resistance appears to be quite similar to the other echinocandins, but may have a higher barrier to resistance given its pharmacological advantages including high C_{max} and prolonged half-life (Locke *et al.*, 2016). In contrast, ibrexafungerp is quite interesting in that it targets glucan synthase slightly differently than the echinocandins, and therefore it has been shown that specific mutational changes both within and outside of the traditional hot-spot locations of FKS1/2 (Jimenez-Ortigosa *et al.*, 2017), are necessary to produce resistance. Therefore, ibrexafungerp resistance does not necessarily overlap with echinocandin resistance, which helps explain surveillance susceptibility data in which ibrexafungerp has been found to have relatively low MICs for a number of echinocandin resistant isolates (Jimenez-Ortigosa *et al.*, 2014; Pfaller *et al.*, 2013) and has been effective in animal models with echinocandin resistant isolates (Wiederhold *et al.*, 2018).

Biofilm formation is an important aspect, especially within *Candida* spp., allowing for colonization of mucosal surfaces, attachment to medical devices, and persistent human disease within a sequestered environment (Nobile and Johnson, 2015). *Candida* biofilms are a dense, complex extracellular matrix structure composed of organism and host derived proteins and macromolecules (Desai *et al.*, 2014; Gulati and Nobile, 2016; Mitchell *et al.*, 2016). Functionally, it provides a sanctuary from the human immune system and provides a physical barrier for drug penetration that can mediate drug tolerance and/or drug resistance (Desai *et al.*, 2014; Kernien *et al.*, 2017). Pre-clinical in vivo studies examining administration of echinocandins via antifungal lock therapy, whereby the echinocandin is instilled into a biofilm infected central venous catheter and allowed to dwell for significant periods of time, are promising compared to other therapeutic strategies and drug classes (Basas *et al.*, 2019; Salinas *et al.*, 2019). An advantage to echinocandin therapy appears to be the combined direct antifungal effect as well as improving the immune system's ability to target and kill pathogenic yeast within the biofilm (Hoyer *et al.*, 2018; Katragkou *et al.*, 2015; Larkin *et al.*, 2018). Therefore, echinocandins may be the preferred drug class for biofilm-related *Candida* infections pending further clinical studies.

Pharmacokinetics and Pharmacodynamics

Pharmacologic Properties

The pharmacology of the three clinically available echinocandins are relatively similar (Eschenauer *et al.*, 2007; Kauffman and Carver, 2008). They are available in intravenous (IV) form only as they are poorly absorbed through the gastrointestinal system (<10% bioavailability). Each has a relatively long half-life, with caspofungin exhibiting the shortest at 9–11 h, micafungin 11–17 h, and anidulafungin the longest at 24–26 h. Due to this and pharmacodynamic properties (see below), once daily IV administration is clinically utilized for each of the available echinocandins. After IV administration, they distribute widely and effectively into numerous tissue sites including the liver, spleen, lung, and kidney. However, owing to their large, complex structure and high protein binding, they do not penetrate well into the CSF or eye. Indeed, a recent examination of serum and CSF caspofungin levels in 13 patients demonstrated 11 of 13 had below the limit of detection of caspofungin in CSF whilst having therapeutic concentrations in the serum (Strenger *et al.*, 2017). Additionally, urinary excretion of unmetabolized drug is very low for all three leading to limited effectiveness at this site. This latter pharmacokinetic property also means that dose adjustments for renal impairment are unnecessary for the group. The echinocandins are metabolized to inactive metabolites in the tissues, which are primarily excreted by the biliary system. Finally, in general the echinocandins are very well tolerated without significant toxicities or adverse effects. In fact, due to their safety profile, they are often the agents of choice for prophylaxis or treatment in those with significant organ dysfunction and most notably, in those with significant liver disease or serious drug interactions where triazoles are contraindicated (Andes *et al.*, 2016; Shibata *et al.*, 2017; Verma *et al.*, 2017). Therefore, the main limiting factor in echinocandin use is the need for once daily IV administration, which necessitates maintenance of intravenous access over prolonged periods in already at risk populations of patients, such as immunosuppressed hematology-oncology patients. The two novel therapies in development, rezafungin and ibrexafungerp, both aim to mitigate this limitation through different pharmacological properties.

Rezafungin, a novel echinocandin in pre-clinical development, exhibits similar bioavailability, distribution, metabolism, and safety as the three approved echinocandins. One significant difference though is worth noting. Rezafungin exhibits a prolonged T_{1/2} of approximately 80 h following the first dose and 150 h following subsequent doses (Sandison *et al.*, 2017). This property makes once weekly intravenous dosing for the treatment or prevention of fungal infection a possibility for rezafungin, for which it is currently in clinical trials.

Ibrexafungerp, a non-echinocandin glucan synthase inhibitor, is currently in pre-clinical trials for the treatment of *Candida* spp or *Aspergillus* spp infections. Oral bioavailability is significantly higher at 35%–51% (Davis *et al.*, 2019) compared to the echinocandins, allowing for both IV and oral formulations. While still in development, it appears that it follows similar other pharmacological properties as the echinocandins in terms of distribution, tissue penetration, half-life, metabolism and elimination.

There is significant limitation, though, to highly homogenous phase I/II preclinical studies to characterize drug pharmacokinetics. Many patients in whom these therapies are ultimately used are quite heterogeneous, with highly variable physiology as well as numerous confounding comorbid diseases and clinical conditions. This can lead to discrepancies between the predicted

pharmacokinetic exposures (e.g., AUC) based on preclinical studies and the observed pharmacokinetic exposures, for example, in a population of critically ill patients. Therefore, in recent years, pharmacokinetic characterization has been undertaken in patients, most commonly those critically ill in the intensive care unit (ICU), as this population is most at risk for exposure variability due to altered distribution, metabolism, and elimination of drugs (Parker *et al.*, 2015). Data is consistent between the three approved echinocandins in that lower than expected drug exposures are noted in ICU patients, with significant covariates that predict suboptimal exposures including increased body weight (i.e., obesity), increased severity score (e.g., SOFA or APACHE), and hypoalbuminemia (Boonstra *et al.*, 2017; Bruggemann *et al.*, 2017; Ferriols-Lisart *et al.*, 2017; Garcia-de-Lorenzo *et al.*, 2016; Jullien *et al.*, 2017; Lempers *et al.*, 2015; Maseda *et al.*, 2018; Wasmann *et al.*, 2019). When evaluated from a pharmacodynamic perspective, many of these studies demonstrated that dose escalation of 1.5–3x the usual dosage may be necessary, especially for obese patients or those with very high severity scores, to optimize AUC exposures and achieve the pharmacodynamic target exposures in this patient population. Another area of concern in terms of suboptimal exposures in clinical medicine occurs for those patients in the ICU on continuous renal replacement (i.e., hemodialysis) therapy. In general, echinocandin exposures are not affected by continuous venovenous hemodiafiltration (Aguilar *et al.*, 2014; Perez-Pitarch *et al.*, 2018; Roger *et al.*, 2017; Vossen *et al.*, 2017). However, these studies did demonstrate that echinocandin exposures were lower than expected for many of these critically ill patients on hemodialysis, confirming the aforementioned studies that critically ill patients may have suboptimal exposures. It should be noted, however, specific differences in drug adsorption to newer dialysis membranes, and in particular AN69 surface-treated and polymethylmethacrylate filters, has been observed suggesting adsorption and need for dose adjustments in CRRT may need to be evaluated with further developments in dialysis filtration technology (Honore *et al.*, 2014). Additionally, extracorporeal membrane oxygenation (ECMO), has become an important respiratory and cardiac life support system utilized in a number of clinical scenarios. However, the ECMO circuit and system can lead to drug extraction and sequestration, thus lowering physiological exposure to the patient. Indeed, over a 4 h period micafungin loss was almost 50% in an experimental ECMO circuit, and by 24 h loss was approximately 75% (Watt *et al.*, 2017). Given the diversity of ECMO and hemofiltration technology, including but not limited to filter chemistry, types of plastics, and coatings/polymers within the systems, ongoing evaluation of these technologies and how they impact drug pharmacokinetics is needed. This also suggests that development and utilization of a therapeutic drug monitoring assay to perform dose adjustments based on individual drug concentrations may be an important aspect of future clinical care for certain patient populations.

Pharmacodynamics

The study of pharmacodynamics integrates drug pharmacokinetics, a measure of in vitro drug potency (MIC), and therapeutic effect (Craig, 1998; Drusano, 2007). The overarching goal is to identify exposure-response relationships that predict therapeutic efficacy in order to design optimal dosing regimens for clinical use as well as set clinical susceptibility breakpoints. Practically, this involves [1] determining which of three PK/PD indices – 24 h Area under the drug concentration curve (AUC)/MIC, Maximum concentration (C_{max})/MIC, or the percentage of the dosing interval in which drug concentrations exceed the MIC (Time > MIC) – correlates with efficacy, and [2] what is the magnitude of that PK/PD index associated with a specific therapeutic outcome such as net stasis or 1-log reduction in burden. In general, pharmacodynamic studies may be performed using in vitro models (e.g., hollow-fiber) or in vivo models (e.g., immune compromised mouse). As a group, the echinocandins have been studied extensively utilizing both methods. Results from studies specifically examining exposure-response relationships for micafungin, caspofungin, and anidulafungin against *Candida* spp have demonstrated concentration-dependent killing effects and prolonged post-antifungal effects (Andes *et al.*, 2008a,b; Ernst *et al.*, 1999, 2002; Gumbo *et al.*, 2006; Louie *et al.*, 2005). Both C_{max}/MIC and 24 h AUC/MIC have been shown to be the pharmacodynamic indices associated with therapeutic effect. Similar results in experimental studies against *Aspergillus* spp have been observed (Groll *et al.*, 2001; Petraitiene *et al.*, 2002; Petraitis *et al.*, 1998, 2002; Wiederhold *et al.*, 2004), as well as more contemporary studies with rezafungin and ibrexafungerp (Lakota *et al.*, 2017; Lepak *et al.*, 2015, 2018a,b, 2019). These results indicate the most efficacious method to administer these drugs to patients is via large, infrequent doses to maximize C_{max} and AUC exposures. Additionally, given the prolonged half-life's and favorable safety profile, investigations into escalating doses and administering even less frequently (as infrequently as once weekly) has been successfully demonstrated in animal models (Gumbo *et al.*, 2007; Lepak *et al.*, 2016) and patient pharmacokinetic studies (Muilwijk *et al.*, 2018). As discussed above, rezafungin, with its significantly prolonged half-life, has been shown in animal model studies to be effective therapy in extended interval dosing design, and clinical studies are underway utilizing a once-weekly dosing schedule to take advantage of the pharmacokinetic and pharmacodynamic profile of this agent.

Pharmacodynamic target exposures have been explored for a variety of *Candida* spp in studies that have varied from 24 to 96 h depending on infecting pathogen (Andes *et al.*, 2010, 2008a,b; Lepak *et al.*, 2012, 2015, 2018a, 2019, 2017, 2018b). It is generally accepted that free drug concentrations are microbiologically active while protein bound drug is inactive, thus having accurate protein binding estimates and correcting for protein binding by reporting free drug PD target exposures, is critically important especially when protein binding is quite high as is the case for the echinocandins. Outcomes examined in these studies include the PD exposure (24 h AUC/MIC) necessary to produce a net static effect (fungal burden at the start of therapy is the same as fungal burden at the end of therapy) and for 1-log decrease in fungal burden (i.e., 1-log kill). Free drug 24 h AUC/MIC targets for net stasis against *C. albicans* have varied between 12 and 28 for micafungin, caspofungin, and anidulafungin. Target exposures for *C. glabrata* and *C. parapsilosis* have been consistently lower with ranges of 2.9–14 and 5–17, respectively. Interestingly, similar studies

often utilizing the same isolates in studies with rezafungin and ibrexafungerp have demonstrated numerically lower PD target exposures. In the case of rezafungin, this may be due to the extremely long half-life with very high loading concentrations upfront in order to maintain 24 h AUCs over the 7 day treatment period (Lakota *et al.*, 2017). The only drugs to be studied, from a pharmacodynamic perspective, against other *Candida* species include micafungin and rezafungin. Both have shown promising effects and exposure response relationships against *C. auris* (Lepak *et al.*, 2018a, 2017), and rezafungin additionally against *C. tropicalis* and *C. dubliniensis* (Lepak *et al.*, 2019). PD target studies against *Aspergillus* spp are limited, primarily due to the fact that this drug class slows hyphal growth at the tips but does not kill the fungus.

Clinical Use of Echinocandins

Multiple clinical trials have been performed with micafungin (de Wet *et al.*, 2004, 2005; Huang *et al.*, 2012; Kohno *et al.*, 2004; Kuse *et al.*, 2007; Ostrosky-Zeichner *et al.*, 2005; Pappas *et al.*, 2007; van Burik *et al.*, 2004), caspofungin (Arathoon *et al.*, 2002; Betts *et al.*, 2009; Kartsonis *et al.*, 2002; Mora-Duarte *et al.*, 2002; Ostrosky-Zeichner *et al.*, 2014; Villanueva *et al.*, 2001, 2002), and anidulafungin (Krause *et al.*, 2004a,b; Reboli *et al.*, 2007; Ruhnke *et al.*, 2012; Winston *et al.*, 2014). In these trials, echinocandins have been demonstrated to be safe and effective for prevention of fungal infection, empiric therapy for those with suspected fungal infection, and for the treatment of candidiasis. Currently, the major role for echinocandin use is the latter, and specifically as a first-line (i.e., preferred agent) for patients with invasive candidiasis. Initially, clinical trials were able to demonstrate a clear safety advantage and potential efficacy advantages of echinocandins over amphotericin B (Arathoon *et al.*, 2002; Kuse *et al.*, 2007; Mora-Duarte *et al.*, 2002; Villanueva *et al.*, 2001). Against fluconazole, individual trials often showed relatively comparative safety and efficacy of fluconazole versus echinocandins for the treatment of candidiasis (de Wet *et al.*, 2004, 2005; Krause *et al.*, 2004b; Villanueva *et al.*, 2002). A meta-analysis of randomized controlled trials in patients with Candidemia or invasive candidiasis demonstrated two factors critical to improved patient survival: echinocandin use for initial therapy and removal of infected central venous catheters (Andes *et al.*, 2012). A more recent randomized controlled trial confirmed these results where isavuconazole was shown to be not non-inferior to caspofungin for the treatment of invasive candidiasis in adults (Kullberg *et al.*, 2019). Response rates were significantly improved in caspofungin treated patients, although it should be noted that mortality (a secondary endpoint) was not significantly different between the two. Nonetheless, based on the evidence, echinocandins have become the preferred initial therapy for patients (adults and children) with candidemia or invasive candidiasis based on both their safety and efficacy (Andes *et al.*, 2012; Pappas *et al.*, 2016; Tsekoura *et al.*, 2019).

A number of studies have also examined the use of echinocandins as prophylaxis for at risk populations (e.g., neutropenic patients) to prevent infection and in general have performed better than fluconazole, presumably due to additional effects against *Aspergillus* spp (van Burik *et al.*, 2004; Winston *et al.*, 2014). The use of echinocandins, though, for prophylaxis is limited with the development of newer triazoles, such as posaconazole, that are extremely effective in prophylaxis settings to prevent mold infections. Thus, echinocandin use for prophylaxis is clinically limited to situations in which triazoles are contraindicated or for certain populations in which *Candida* infections are particularly more likely than filamentous fungal infections, for example liver transplant recipients. Additionally, while the echinocandins are largely interchangeable, only caspofungin has FDA label approval for febrile neutropenia and micafungin has FDA labeled approval for fungal prophylaxis in neutropenia (Drugs@FDA, n.d.).

The use of echinocandins as prophylaxis or empiric therapy for those with risk factors for or clinically suspected invasive candidiasis is a more nuanced situation. For patients in the ICU, who are at risk for central line infections and intra-abdominal infections where *Candida* may play a prominent role as infecting pathogen, a number of trials have failed to show benefit to prophylaxis or pre-emptive approach to antifungal therapy, including echinocandins (Knitsch *et al.*, 2015; Ostrosky-Zeichner *et al.*, 2014; Pelz *et al.*, 2001; Schuster *et al.*, 2008; Timsit *et al.*, 2016). That being said, there may be clinical factors that lead to a high suspicion of invasive candidiasis, and whether empirical use of an echinocandin versus fluconazole may be preferred for these patients often hinges on the local incidence (Lepak and Andes, 2011). Thus, as a matter of routine in the ICU, echinocandin prophylaxis, pre-emptive, or empirical therapy cannot be recommended at this time.

Echinocandin studies against invasive aspergillosis are limited and only caspofungin carries labeled approval for salvage therapy in patients refractory to or intolerant of first-line options (Drugs@FDA, n.d.) such as voriconazole and isavuconazole. Clinical studies have examined caspofungin use as first-line or second-line therapies, but are limited by their non-randomized or retrospective design, heterogenous patient populations and wide response rates (Cornely *et al.*, 2011; Egerer *et al.*, 2012; Herbrecht *et al.*, 2010; Kartsonis *et al.*, 2005; Maertens *et al.*, 2006, 2004; Viscoli *et al.*, 2009). Data exists for micafungin demonstrating similar response rates as caspofungin (Denning *et al.*, 2006; Ji *et al.*, 2017; Kontoyannis *et al.*, 2009). Anidulafungin monotherapy data for invasive aspergillosis consists of case-reports only. Anidulafungin was however, a component of the largest randomized, double-blinded, placebo-controlled trial examining the effects of combination therapy (Marr *et al.*, 2015). Prior to this, numerous pre-clinical in vitro and in vivo models, as well as uncontrolled retrospective studies, had suggested combination therapy consisting of an echinocandin with a triazole (such as voriconazole, posaconazole, or isavuconazole) may be more beneficial than monotherapy with a triazole alone. The primary outcome was mortality at 6-weeks, which was not statistically different between voriconazole monotherapy and voriconazole with anidulafungin. There was a trend in favor of combination therapy and in certain subgroups. The newer therapies, rezafungin and ibrexafungerp, are currently in clinical trials and their role in therapy remains to be determined at this point.

Echinocandins in Special Populations

Pediatrics

Echinocandin use in pediatric patients has dramatically risen as studies and formal approval for pediatric use has matriculated over the last decade in Europe and the United States. In fact, echinocandin use in hospitalized children increased over 300% from 2005 to 2015 in the United States (Downes *et al.*, 2018). Pediatric use of echinocandins is mainly limited to micafungin and caspofungin, both of which have sufficient studies to warrant approval for pediatric specific indications and dosing.

Micafungin has been studied and approved for use in neonatal and pediatric populations for the treatment of invasive candidiasis, esophageal candidiasis, and for prophylaxis of candida infections in stem cell recipients (Drugs@FDA, n.d.; Manzoni *et al.*, 2014). Original approval was for pediatric patients ≥ 4 months in age with dosages based on weight and indication (varying between 1–3 mg/kg IV daily with a daily maximum of 50–150 mg); however, more recent approval has been added for pediatric patients under 4 months with a recommended dose of 4 mg/kg IV daily (Drugs@FDA, n.d.). It is important to note, though, a number of investigations have demonstrated altered pharmacokinetics in newborns based on both age and weight (Heresi *et al.*, 2006; Seibel *et al.*, 2005), suggesting higher doses may be necessary for pre-term and term neonates (Ascher *et al.*, 2011; Caudle *et al.*, 2012; Hope *et al.*, 2010). Additionally, preclinical rabbit models of *Candida* meningoencephalitis, a rare but recognized complication of invasive candidiasis in the neonatal period, demonstrated that micafungin penetrated brain parenchyma infected by hematogenous seeding during invasive candidiasis and that micafungin could be used successfully for therapy (Hope *et al.*, 2008). The pharmacodynamic targets for successful therapy demonstrated in the in vivo study are, however, optimally met by a dosage range of 10–25 mg/kg IV daily in neonates (Benjamin *et al.*, 2010; Hope *et al.*, 2008; Hope *et al.*, 2010). Additionally, as *Candida* meningoencephalitis can be difficult to diagnose and CSF cultures are not reliably positive in this disease, some suggest that if an echinocandin is to be used in a neonate with candidemia it should likely be used at a dosage of at least 10 mg/kg IV daily. Indeed, a recent phase III study of micafungin at 10 mg/kg in infants with invasive candidiasis was shown to be well tolerated and efficacious for invasive candidiasis (Benjamin *et al.*, 2018). It is important to note, though, that clinical efficacy data for any echinocandin, including micafungin, for use in meningoencephalitis is lacking.

Caspofungin has approval for pediatric patients for the treatment of invasive or esophageal candidiasis, treatment of suspected fungal infection in febrile neutropenia, and additionally has approval for salvage therapy for those with invasive aspergillosis refractory to or intolerant of other therapies for ages 3 months and older (Drugs@FDA, n.d.; Fisher *et al.*, 2019; Tsekoura *et al.*, 2019). Dosing is done in body surface area, with a loading dose of 70 mg/m² IV and maintenance dose of 50 mg/m² IV daily thereafter.

At this time, anidulafungin does not have specific approval in the United States or Europe related to pediatric use. A number of studies and anecdotal reports have been completed with encouraging results (Benjamin *et al.*, 2006; Roilides *et al.*, 2019; Rosanova *et al.*, 2017; Wilke, 2013), but dosing and indication of anidulafungin use in pediatric populations is still in the process of study and refinement.

Geriatric

No dose adjustments are necessary for any of the three approved echinocandins based on age. For each drug, when response and safety data was analyzed based on age, no significant difference was noted between geriatric and younger populations (Drugs@FDA, n.d.). Some pharmacokinetic studies report elevated echinocandin drug exposure in the geriatric population, which could be secondary to changes in lean body mass and volume of distribution, as well as metabolism and drug excretion. For example, caspofungin AUC was approximately 28% higher in the geriatric population (Drugs@FDA, n.d.); however, there was no apparent clinical significance, both in terms of efficacy and safety, from this increased drug exposure.

Pregnancy/Lactation

The echinocandins as a group have been classified as pregnancy class C drugs (Drugs@FDA, n.d.). For each, this designation is largely based on animal studies demonstrating that fetal harm may occur; and for each, there is a lack of sufficient data in pregnant women to adequately establish and/or inform the risk of adverse effects to human embryo and fetal development. Each of the echinocandins is secreted in the milk of lactating rats, but data does not exist to confirm this in humans. Even if present, echinocandins are not absorbable through the gastrointestinal tract, and thus would not be expected to produce a systemic exposure in a breast-feeding infant. That being said, local effects on the infant's gastrointestinal microbiome are plausible. Therefore, a risk: benefit analysis based on the benefits of breastfeeding, the mother's clinical need for echinocandin therapy, potential alternative therapies, and risk of echinocandin gastrointestinal exposure by the infant should be considered.

Drug–Drug Interactions

Echinocandins are poor substrates for hepatic metabolism enzymes (Niwa *et al.*, 2014), and therefore drug-drug interactions are uncommon for the group (Drugs@FDA, n.d.; Patil and Majumdar, 2017). The most clinically important drug interactions are summarized below, and are separated into interactions in which an interacting drug changes (i.e., increases or decreases) the

echinocandin exposure and interactions in which the echinocandin changes the interacting drug's exposure. Two drugs can interact with caspofungin to change the drug exposure. Rifampin reduces caspofungin exposure by approximately 30% and cyclosporine increases caspofungin exposure by approximately 35%. Cyclosporine also interacts with anidulafungin, leading to an anidulafungin AUC increase of approximately 22%. There are no known drug interactions that increase micafungin exposure. Caspofungin interacts with tacrolimus to decrease the tacrolimus exposure by approximately 20%. Micafungin interacts with three drugs, it decreases cyclosporine clearance by approximately 16% and increases sirolimus and nifedipine AUC exposure by about 21% and 18%, respectively. Anidulafungin does not appear to have any interactions that affect the pharmacokinetics of other drugs.

Allylamines, Morpholine Derivatives, Fluoropyrimidines, and Griseofulvin

Kelly Ishida and Vinícius de Moraes Barroso, University of São Paulo, São Paulo, Brazil

Introduction

In this chapter, we address non-polyene, non-echinocandin and non-azole antifungal agents, such as allylamines, morpholine derivatives, fluoropyrimidines, and griseofulvin. These antifungals are commonly used to treat superficial and cutaneous mycoses, frequently caused by dermatophytes, via oral or topical administration. We focus on the brief history, pharmacodynamics and pharmacokinetics, toxicity effects and some strategies to improve the pharmacological characteristics of these antifungals, such as the production of synthetic analogues and the development of new formulations based in drug carrier systems.

Allylamines

The functionalized allylamines are synthetic compounds, with the two main pharmaceutically important representatives being naftifine and terbinafine (Fig. 1). Both are active on dermatophytes and are indicated for treatment of skin and nail mycoses (Petranyl *et al.*, 1984). Allylamines specifically inhibit ergosterol biosynthesis at the squalene epoxidation step by inhibiting squalene epoxidase enzyme, causing a fungistatic or fungicidal effect by the accumulation of a toxic concentration of squalene and ergosterol depletion (Ryder, 1992). This excess of squalene is deposited into lipid vesicles, and these function as lipid sponges that remove lipids from the cell membrane, causing instability and shrinkage, leading to fungal cell death (Ryder, 1992).

Fig. 1 Chemical structures of antifungals allylamines (terbinafine and naftifine), morpholine derivatives (amorolfine), fluoropyrimidines (flucytosine), and griseofulvin.

Naftifine is obtained by acid hydrolysis of heterocyclic spironaphthalenones (Petranyl *et al.*, 1984) and it is considered a fungicide *in vitro* against dermatophytes *Trichophyton* spp., *Microsporum* spp., and *Epidermophyton* spp., but is not active against *Candida* spp. (Georgopoulos *et al.*, 1981). Terbinafine is a synthetic analogue of naftifine (Ryder, 1992); it has a fungicidal effect against dermatophytes and also demonstrates antifungal action against *Candida* spp. and *Cryptococcus* spp. due to a high chemical affinity for squalene epoxidase, but shows variable activity *in vitro* (Barchiesi *et al.*, 1998; Lee and Fothergill, 2003). Both drugs are used topically (cream or gel formulations), but only terbinafine is given orally for systemic absorption due to the increased selectivity (Newland and Abdel-Rahman, 2009).

Terbinafine is unaffected by the presence of food when administered orally and has a bioavailability of 70%–80%, with maximal plasma concentration achieved within 2 h following administration of 250 mg (0.8–1.5 µg/ml) (Jensen, 1990). The terbinafine half-life was calculated to be 0.8–1.2 h and its elimination is approximately 16 h. It is completely metabolized in the liver, generating 15 metabolites that are excreted in the urine; in addition, no parent drug is detected in the urine (Jensen, 1990). Terbinafine is a highly lipophilic and keratinophilic compound and, thus, accumulates in the stratum corneum of the skin and nails (Ryder and Frank, 1992). For this reason, allylamine drugs are used effectively to treat dermatophytosis of the skin and nails (Sahni *et al.*, 2018).

Terbinafine is generally well tolerated, but adverse effects include mild and transient forms associated with its oral administration, such as gastrointestinal symptoms, and its preference for the skin may result in cutaneous rash and urticaria (Friedlander *et al.*, 2002; Elewski *et al.*, 2008).

Although terbinafine is effective in the treatment of skin and nail mycoses mainly caused by dermatophytes, this drug also has *in vitro* antifungal activity against other fungi, such as *Candida* spp., *Cryptococcus* spp., *Aspergillus* spp., *Penicillium marneffei*, *Sporothrix* spp. and chromoblastomycosis agents at low concentrations (Ryder *et al.*, 1998; Barchiesi *et al.*, 1998; Jessup *et al.*, 2000; Kirkpatrick *et al.*, 2005; Mendes *et al.*, 2010; Guerra *et al.*, 2012; Borba-Santos *et al.*, 2015). However, it was less effective against *Blastoschizomyces capitatus* and *Trichosporon beigelii* (Kirkpatrick *et al.*, 2005).

Synergistic *in vitro* antifungal activity has been demonstrated with terbinafine in combination with azoles or amphotericin B for many important fungal pathogens, including *Candida* spp., *Cryptococcus* spp., *Aspergillus* spp., zygomycetes, *Fusarium* spp., *Paecilomyces* spp., dematiaceous molds, and the highly resistant *Scedosporium prolificans* (Vazquez, 2008; Gómez-López *et al.*, 2003; Ortoneda *et al.*, 2004a,b; Barchiesi *et al.*, 1997; Biancalana *et al.*, 2011; Barchiesi *et al.*, 1998; Meletiadiis *et al.*, 2000; Kirkpatrick *et al.*, 2005; Ryder and Leitner, 2001; Guerra *et al.*, 2012). Azole agents and terbinafine block different steps of the ergosterol biosynthesis pathway, supporting the mechanism of synergistic action (Meletiadiis *et al.*, 2000).

In addition to the utilization of terbinafine in the treatment of dermatomycosis, interest has expanded to include its use alone or in combination with azoles for a range of cutaneous and subcutaneous mycoses, such as sporotrichosis, eumycetoma, and chromoblastomycosis (Esterre *et al.*, 1998; Chapman *et al.*, 2004; N'diaye *et al.*, 2006; Dolton *et al.*, 2014), and to treat resistant or refractory fungal infections (candidiasis, cryptococcosis and aspergillosis), as is described in numerous reported cases (Revankar *et al.*, 2008; Villars and Jones, 1992; Schiraldi and Colombo, 1997; Ghannoum and Elewski, 1999; Steinbach *et al.*, 2003; Gómez-López *et al.*, 2003; Krishnan-Natesan *et al.*, 2008).

There are few studies on resistance to allylamines; one of the limitations for this is the lack of standardized susceptibility testing to antifungals for dermatophyte fungi. Recently, 15 *T. interdigitale* and 5 *T. rubrum* isolates exhibiting high MIC values for terbinafine were evaluated for mutations in the squalene epoxidase gene, and the higher tolerance to terbinafine was related to a change of phenylalanine to leucine in the 397th position of the target enzyme, which may lead to a failure of terbinafine to block ergosterol biosynthesis (Rudramurthy *et al.*, 2018).

New formulations are being developed to reduce allylamine drug toxicity, to increase skin penetration, and to improve biodistribution and antifungal efficacy. Formulations based in colloidal nanocarriers containing naftifine were assayed in models *in vitro* in pig skin and *in vivo* in human skin; these nanocarriers increased transport of naftifine into deeper layers of the skin, improving topical drug delivery (Erdal *et al.*, 2016). Terbinafine contained in lipid- and polymeric-based carriers were also developed and tested on animal models of fungal infections (Chen *et al.*, 2012; Vaghasiya *et al.*, 2013; Wavikar and Vavia, 2013; Tayel *et al.*, 2013). The terbinafine in lipid nanoparticles caused a significant reduction in *C. albicans* CFU counts compared to the conventional formulation (Wavikar and Vavia, 2013; Vaghasiya *et al.*, 2013). The formulation of terbinafine-loaded solid lipid nanoparticles was also shown to significantly increase penetration of the skin layers, increasing its bioavailability (Chen *et al.*, 2012). Terbinafine in polymeric nanoparticles (composed of chitosan, soybean lectin or Pluronic® F68) was tested in a *Fusarium* fungal corneal keratitis model and was able to increase ocular bioavailability of terbinafine by twofold compared to the conventional formulation (Tayel *et al.*, 2013).

Another important strategy for improving the pharmacokinetic profile and antifungal activity of allylamines is the synthesis of structural analogues. Some naftifine analogues were shown to have activity on *T. rubrum* and *T. mentagrophytes* *in vitro*, and had even greater effects on yeasts, such as *C. neoformans* and *C. albicans* (Abonia *et al.*, 2018); terbinafine analogues were screened for antifungal activity against *C. albicans*, and similar results to terbinafine were found (Kharkar *et al.*, 2009).

In addition, butenafine is a benzylamine derivative that also shows potent fungicidal activity, particularly against etiological agents of superficial mycoses, dermatophytes, *Aspergillus*, and dimorphic and dematiaceous fungi (Singal, 2008). Its mechanism of action is similar to allylamines, and a cream formulation is recommended for the treatment of interdigital tinea pedis, tinea cruris, and tinea corporis (Singal, 2008; El-Gohary *et al.*, 2014).

Morpholine Derivatives

Morpholine derivatives are synthetic heterocyclic compounds containing amine and ether functional groups. They have demonstrated inhibitory activity on plant, animal and human pathogenic fungi (Polak, 1983). Among the morpholine derivatives, amorolfine (Fig. 1) is the most studied molecule and is used in the treatment of human fungal disease; nevertheless, in agriculture, aldimorph, fenpropimorph, fenpropidin, tridemorph, and dodemorph are used as fungicides and are highly toxic for human use (Jachak *et al.*, 2015).

Morpholine derivatives are ergosterol biosynthesis inhibitors, which may have a fungicidal effect against the most fungal species (Haria and Bryson, 1995). The antifungal activity occurs by the inhibition of two enzymes, Δ^8 - Δ^7 isomerase and sterol Δ^{14} -reductase, in the post-lanosterol/cycloartenol step of the ergosterol biosynthetic pathway, which leads to ergosterol depletion and the accumulation of intermediates, ignosterol and lichesterol (Müller *et al.*, 2013). Treatment with amorolfine may lead to morphological changes in fungal cells, such as shortening of germ tubes, enlargement in the diameter of hyphae, excessive branching in *Botrytis* spp. and in the dermatophytes (Polak, 1988). In addition, the cell wall thickness is significantly increased and chitin deposits are included inside and outside (Polak, 1992). This fungicidal effect is dependent on both the drug concentration and the exposure time (Polak-Wyss, 1995).

Currently, the morpholine derivative amorolfine is recommended to treat dermatophytosis in human skin and nails (Kaul *et al.*, 2017). In *in vitro* assays, dermatophytes (~15 species) are susceptible to amorolfine at concentrations lower than 2 µg/ml (Adimi *et al.*, 2013; Favre *et al.*, 2003; Li *et al.*, 2004). Polak (1992) also demonstrated the antifungal efficacy of amorolfine on dermatophytes, and against other fungi; however, it did not appear to be effective when given orally. Mice infected with *T. mentagrophytes* responded to the combined therapy of amorolfine with terbinafine, itraconazole or griseofulvin in a dose-dependent manner, showing a significant reduction in the appearance of mycotic foci compared to untreated animals (Polak-Wyss, 1995).

Topical amorolfine nail lacquer 5% is commonly used for the treatment of human onychomycosis as a monotherapy or in combination with other antifungals, such as griseofulvin, ketoconazole, itraconazole or terbinafine (Haria and Bryson, 1995; Polak *et al.*, 2004); importantly, amorolfine in combination with systemic antifungal agents was better than the monotherapy using itraconazole or terbinafine (Feng *et al.*, 2017).

Administration of amorolfine nail lacquer 5% once or twice weekly is 60%–71% effective in the treatment of toenail onychomycosis, and complete cure is observed after six months of the antifungal therapy in 38%–46% of patients (Hay, 2010). Following topical application of amorolfine, the rate of absorption through the human thumbnail reaches an initial peak after 5 h and decreases slightly, then rises again to peak higher still at 25 h and decreases slightly (Franz, 1992).

Research to improve the antifungal efficacy of morpholine derivatives is ongoing. Jachak *et al.* (2015) synthesized modified morpholines with incorporated silicon, which exhibited potent antifungal activity against *C. albicans*, *C. glabrata*, *C. tropicalis* and *C. neoformans* (MICs from 0.25 to 4 µg/ml), similar to the results observed with amorolfine (MICs from 0.125 to 1 µg/ml).

Fluoropyrimidines

The anticancer and antimicrobial activities of fluoropyrimidines were first described in 1957 by Heidelberger and collaborators. The fluoropyrimidines, such as 5-fluorouracil (5-FU), capecitabine and tegafur, are antimetabolite drugs widely used in the treatment of colorectal and breast cancers (Wilson *et al.*, 2014). The mechanism of action of fluoropyrimidines consists of the erroneous incorporation of 5-FU into RNA and DNA and inhibition of thymidylate synthase (TYMS), which results in the inhibition of protein and DNA biosynthesis (Wilson *et al.*, 2014).

5-fluorocytosine (flucytosine or 5-FC, Fig. 1) is also an antimetabolite drug, being a fluorinated analogue of cytosine. It was synthesized in 1957 at Roche Laboratories as potential anticancer agent, but did not demonstrate to be effective in tumor treatment (Heidelberger *et al.*, 1957; Heidelberger *et al.*, 1958). Years later, 5-FC showed antifungal efficacy using murine models of candidiasis and cryptococcosis, and was recommended for treatment of both invasive fungal infections thereafter. Although 5-FC has high antifungal activity on *Candida* and *Cryptococcus*, it was also shown to have lesser inhibitory effects on *Aspergillus* spp., dematiaceous fungi and etiological agents of chromomycosis, such as *Phialophora* spp., *Cladosporium* spp. and *Exophiala* spp. (Benson and Nahata, 1988).

5-FC itself has no antifungal effect. It must be taken up by the fungal cells via a transporter, cytosine permease, and converted first into 5-fluorouracil (5-FU) by cytosine deaminase, and then into the metabolite 5-fluorodeoxyuridine, which inhibits RNA and DNA synthesis (Polak and Scholer, 1980; Polak, 1977). The conversion from 5-FC to 5-FU inside the fungal cell is a crucial step for the antifungal effect, as fungi lacking cytosine deaminase are not sensitive to 5-FC (Polak and Scholer, 1980; Polak, 1977).

Unfortunately, 5-FC as a single antifungal agent in clinical use is problematic owing to its relatively weak antifungal efficacy and the fast development of fungal resistance by gene mutations in cytosine permease or cytosine deaminase (Polak, 1977). A 5-FC primary resistance rate of 1%–7% is observed for *Candida* and *Cryptococcus* isolates (Cuenca-Estrella *et al.*, 2001; Govender *et al.*, 2011; Loyse *et al.*, 2013). Thus, 5-FC in monotherapy is not recommended; only 5-FC in combination with amphotericin B has been proven to be synergistic for the treatment of cryptococcosis using *in vitro* assays, animal models and clinical trials (Montgomerie *et al.*, 1975; Schwarz *et al.*, 2006; Schwarz *et al.*, 2007; Dromer *et al.*, 2008). Currently, 5-FC combined with amphotericin B for 2 weeks followed by maintenance with fluconazole has been considered the gold standard treatment for cryptococcal meningitis (Perfect *et al.*, 2010; World Health Organization, 2018). Other synergistic combinations, such as 5-FC with caspofungin, were also evaluated for the treatment of candidiasis (Charlier *et al.*, 2015).

5-FC is available in tablet form (250 and 500 mg) and as an intravenous formulation (10 mg/mL in saline) (World Health Organization, 2007). It is well absorbed by the gastrointestinal tract (76%–89%), with peak plasma concentration occurring approximately 2 h after oral administration (Cutler *et al.*, 1978; Vermes *et al.*, 2000). Because 5-FC is soluble in water, it gets into the urine, peritoneal fluid, cardiac tissue and the eye in sufficient concentrations. 5-FC also has great blood-brain barrier penetration, an important characteristic for the treatment of cryptococcal meningitis (Daneshmend and Warnock, 1983; Kethireddy and Andes, 2007).

5-FC is excreted almost entirely by glomerular filtration (90%) and dose reduction is necessary for patients with renal dysfunction (Cutler *et al.*, 1978). 5-FC can cause renal toxicity, and for this reason, it is important to monitor renal function during 5-FC clinical use (Vermes *et al.*, 2000).

Oral 5-FC is generally well tolerated by patients because mammalian cells do not have cytosine deaminase (Vermes *et al.*, 2000); however, it occasionally causes gastrointestinal symptoms, such as nausea and diarrhea, skin rashes and suppression of bone marrow function (Vermes *et al.*, 2000). At high 5-FC serum levels, a transient hepatomegaly and altered transaminases may be observed. 5-FC also induces teratogenic effects at concentrations lower than those used for treatment of cryptococcal meningitis (Vermes *et al.*, 2000).

5-FC derivatives had been synthesized with the aim of increasing antifungal activity and reducing the rate of resistance development. Pyrimidin-one and -thione (often known as DHPMs), structural analogues of 5-FC, were tested in combination with amphotericin B or fluconazole for activity against *Candida albicans* strains and showed synergistic antifungal effects *in vitro*, which could lower the required dosages of antifungal drugs for the treatment of invasive fungal diseases (Wani *et al.*, 2017).

In the design of new drugs, the hybridization approach is a worldwide practice strategy for developing molecules with higher activity and less drug resistance due to the possible alternative action mechanisms of hybrids (Fang *et al.*, 2017). Hybrids of 5-FC and fluconazole were designed and synthesized and presented potential antifungal effects (Fang *et al.*, 2017).

Griseofulvin

Griseofulvin was isolated from *Penicillium griseofulvin* in its pure form for the first time by Brian and collaborators in 1939 (Oxford *et al.*, 1939), and its chemical structure was elucidated between 1952 and 1959 (Petersen *et al.*, 2014) (Fig. 1). Griseofulvin is a secondary metabolite, which can also be produced by other fungi genus as *Aspergillus*, but the majority of these are found in *Penicillium*, where at least 16 species are known to be griseofulvin producers (Larsen *et al.*, 2005).

The natural product griseofulvin is an antifungal used for treatment of superficial mycoses and dermatophytosis in humans and animals (Gull and Trinci, 1973). In the last decade, there has been a renewed interest in griseofulvin due to its antimitotic and antiproliferative activities against various types of cancer cells and antiviral effects (Petersen *et al.*, 2014). The mode of action of griseofulvin is still poorly understood, but disruption of microtubule dynamics in both fungal and mammalian cells has been proposed (Osment, 1969; Gull and Trinci, 1973; Petersen *et al.*, 2014).

Griseofulvin has a fungistatic action by inhibition of microtubule assembly; it interacts with microtubules to affect the formation of the mitotic spindle, causing abnormal chromosomal rearrangements and, as a final consequence, inhibits fungal replication (Gull and Trinci, 1973). It has *in vitro* activity mainly on several species of *Microsporum*, *Epidermophyton* and *Trichophyton*, which are responsible for hair and skin diseases (dermatophytosis) in both humans and animals (Gentles, 1958; Moriello and DeBoer, 1995; Chadeganipour *et al.*, 2004; Gupta *et al.*, 2009).

Patients presenting long-standing onychomycoses had been treated with griseofulvin previously, demonstrating limited therapeutic success (Scholz and Meinhof, 1991); and higher MIC values of griseofulvin may be associated with therapeutic failure (Gupta *et al.*, 2009). Griseofulvin is currently not recommended for treatment in monotherapy, as there are other alternatives, such as allylamines, amorolfine and azoles (Rajagopalan *et al.*, 2018). Although a large variety of oral and topical antifungal protocols are available for the treatment of dermatophytosis, the efficacy of these drugs is variable, with treatment failure occurring in up to 40% of patients, possibly due to resistance phenomena, as with the treatment of *M. canis* infection, for example (Aneke *et al.*, 2018).

Griseofulvin can be administered topically or orally as a crystal suspension. It is poorly absorbed by the gastrointestinal tract due to its low water solubility, and varies considerably; absorption is increased by decreasing of the crystal size associated with a greasy diet (Steinbach and Dvorak, 2012). Griseofulvin is deposited in keratin precursor cells and becomes bound to newly formed keratin (Steinbach and Dvorak, 2012). It is metabolized by liver microsomal enzymes and excreted in the urine and feces (Gupta *et al.*, 1994).

Griseofulvin has a long-standing history of safety; however, some side effects have been described, such as cutaneous rash, urticaria, nausea, vomiting, diarrhea, headache, fatigue, proteinuria and leukopenia (Steinbach and Dvorak, 2012). Because it is metabolized in the liver, increases of hepatic enzymes in the serum can occur (Steinbach and Dvorak, 2012).

Analogues of griseofulvin have been isolated for their antifungal and anticancer activity. The first griseofulvin analogue bearing an N-isopentane moiety, and the first example of a naturally occurring N-containing griseofulvin derivative, was isolated from *Penicillium griseofulvum* CPCC 400528 (Zhang *et al.*, 2017). Other griseofulvin analogues were also isolated from the mushroom, *Xylaria cubensis* (Paguigan *et al.*, 2017). In addition, fluorinated analogues were synthesized from previously isolated griseofulvin, and these compounds were strongly active against a panel of cancer cell lines and demonstrated antifungal activity against *Microsporum gypseum* (Paguigan *et al.*, 2017). Thus, aside from being an antifungal drug, griseofulvin and its derivatives may also be a clinically-viable candidate for cancer chemotherapy.

Introduction

Disease and death caused by fungal infections have transitioned from a rare curiosity to a major global health problem (Robbins *et al.*, 2016). An estimated 1.5–2 million people die of fungal infections each year (Denning and Jugessur, 2016). The therapeutic arsenal has been limited, and the available antifungal drugs actually suffer from limitations in the route of administration, high toxicity, a narrow spectrum of activity, detrimental drug interactions, the development of drug resistance, and poor bioavailability in target tissues (Brown *et al.*, 2012).

In this context, new safe molecules with efficient antifungal activities are needed. In this chapter, we discuss some of the alternatives to conventional antifungals for treating fungal diseases. New targets in fungal cells for the development of new antifungals, including inhibitors of chitin synthesis, protein and lipid synthesis, efflux and proton pumps and folate synthesis, as well as cell stress regulators and molecules from drug repurposing, are described here (details are shown in Table 1). Some of these molecules are in the clinical trial phase (I and II), while others are still in preclinical phase studies.

Cell Wall

GPI Anchor

APX001, the N-phosphonooxymethyl prodrug of APX001A, is a first-in-class broad-spectrum antifungal compound that inhibits Gwt1, an enzyme which is required for cell wall localization of glycosylphosphatidylinositol (GPI)-anchored mannoproteins in fungi (Zhao *et al.*, 2018; Viriyakosol *et al.*, 2019). The active compound, APX001A, demonstrated potent *in vitro* activity against clinically important fungal species, including echinocandin- and fluconazole-resistant isolates (Pfaller *et al.*, 2019). The antifungal efficacy of APX001 was demonstrated in *in vivo* murine models of systemic candidiasis with *Candida albicans* and *Candida auris* (Zhao *et al.*, 2018; Wiederhold *et al.*, 2019) and invasive pulmonary aspergillosis (Gebremariam *et al.*, 2018); APX001 alone or in combination with fluconazole was effective in the treatment of cryptococcal meningitis (Shaw *et al.*, 2018). In addition, APX001 and its derivatives were also highly effective *in vitro* against *Coccidioides* spp. isolates, and *in vivo* against *Coccidioides immitis* in an experimental pneumonia mouse model, reducing fungal burden in the lungs and preventing dissemination, similarly to fluconazole (Viriyakosol *et al.*, 2019). The preclinical efficacy and safety data lend support to the clinical trials (phase II), now in the patient recruitment phase, that will evaluate the efficacy and safety of APX001 in patients with candidemia (NCT03604705).

Chitin Synthase

Nikkomycins X and Z, isolated from *Streptomyces tendae* (Tu 901 strain) (Dähn *et al.*, 1976), are competitive inhibitors of chitin synthase, which is responsible for chitin polymer production, an important component of the fungal cell wall (Hector *et al.*, 1990; Gaughran *et al.*, 1994). Nikkomycins X and Z showed promising *in vitro* activity against *C. albicans* and *C. immitis* (McCarthy *et al.*, 1985; Hector *et al.*, 1990), and the synergistic effect of nikkomycin Z with echinocandins or azoles was shown against *C. albicans*, *Candida glabrata*, and *Aspergillus fumigatus* *in vitro* (Li and Rinaldi, 1999; Ganesan *et al.*, 2004; Sandovsky-Losica *et al.*, 2008; Verwer *et al.*, 2012; Kovács *et al.*, 2019). Nikkomycin Z was found to be highly effective for the treatment of coccidioidomycosis in animal models (Hector *et al.*, 1990; Shubitz *et al.*, 2013). Notably, nikkomycins had pronounced antifungal activity against *C. immitis* due to the higher chitin content in the cell wall (Li and Rinaldi, 1999). Importantly, clinical trials for nikkomycin Z had been conducted, in which its safety and pharmacokinetics were evaluated in both healthy individuals and those diagnosed with *Coccidioides* pneumonia (NCT00614666 and NCT00834184) (Nix *et al.*, 2009). Unfortunately, the spectrum of activity of nikkomycin Z on other systemic mycoses is limited; as a result, studies were conducted to improve its efficacy. Novel nikkomycin analogs, Px and Pz, developed by mutasynthesis, showed strong inhibitory activity on *C. albicans* (Niu and Tan, 2013; Feng *et al.*, 2014). Structural analogs were synthesized with enhanced chitin synthase inhibitory activity in *C. albicans* (Obi *et al.*, 2000).

Lipids

Acetyl-CoA Synthetase

AR-12 is a celecoxib derivative that inhibits the activity of acetyl-CoA synthetase (ACs), an enzyme involved with acetate metabolism, in fungal cells. In most yeast species, acetate represents an important carbon source for the generation of acetyl-CoA; ACs

Table 1 New targets and antifungal compounds

Compounds	Molecular target	Target species	MIC values	In vivo
APX001	GPI synthesis	<i>Candida</i> spp., <i>Cryptococcus</i> spp., <i>Aspergillus</i> spp., <i>Scedosporium</i> spp.	0.008–0.5 µg/ml	Candidiasis, cryptococcosis, aspergilosis and coccidioidomycosis (murine)
Nikkomycins Z and X	Chitin synthase enzyme	<i>Candida</i> spp., <i>C. immitis</i>	0.77–0.25 µg/ml synergism with azoles and echinocandins	Coccidioidomycosis (murine)
AR-12	Acetyl-CoA synthetase	<i>Candida</i> spp., <i>C. neoformans</i> , <i>Fusarium</i> spp., <i>B. dermatiditis</i> , <i>H. capsulatum</i> , <i>C. immitis</i>	1–4 µg/ml synergism with fluconazole	Cryptococcosis (murine)
Quinoclidines	SQS	<i>Candida</i> spp.	1 to > 16 µg/ml	Not
Celastrol	SQS	<i>Aspergillus</i> spp.	830 nM	Not
Azasterols	24-SMT	<i>C. albicans</i> , <i>C. neoformans</i> , <i>P. brasiliensis</i> , <i>Pneumocystis carinii</i> , <i>P. jirovecii</i>	≤0.06 to > 16 µg/ml 200 nM to 10 µM	Not
Arylguanidines	24-SMT	<i>Candida</i> spp., <i>Aspergillus</i> spp., Dermatophytes	≤0.06 to 16 µg/ml	Not
Aureobasidin A	Ipc1	<i>C. albicans</i> , <i>S. cerevisiae</i> , <i>C. neoformans</i>	0.25 to > 4 µg/ml	Not
Defensins	GlcCer	<i>C. albicans</i>	5–10 µM	Candidiasis (murine)
BHBM and DO	GlcCer	<i>C. neoformans</i> , <i>Candida</i> spp., <i>A. fumigatus</i> , <i>H. capsulatum</i> , <i>Pneumocystis</i> spp.	0.125 to >32 µg/ml	Candidiasis, cryptococcosis and pneumocystosis (murine)
Milbemycin	ABC transporter	<i>Candida</i> spp.	3.2–6.4 µg/ml synergism with azoles	Systemic candidiasis (murine)
Unnarmicin A and C	ABC transporter	<i>S. cerevisiae</i> , <i>C. albicans</i>	80–320 µM synergism with azoles	Not
Tellurides	ABC transporter	<i>S. cerevisiae</i> , <i>C. albicans</i>	100 µM reverse resistance; MIC (2–5 µM) and synergism with azoles	Not
Omeprazole and derivatives	Proton pump	<i>Cryptococcus</i> spp., <i>Candida</i> spp., <i>S. cerevisiae</i> , <i>A. fumigatus</i>	0.06–1000 µg/ml synergism with azoles	Not
Sordarins	Fungal elongation factor 2 (EF2)	<i>Candida</i> spp., <i>C. neoformans</i> , <i>P. carinii</i> (currently named <i>P. jirovecii</i>), filamentous fungi	0.004 to >64 µg/ml	Candidiasis and histoplasmosis (murine)
Tavaborole	tRNA synthetase	Dermatophytes, <i>Candida</i> spp., <i>C. neoformans</i> , <i>Malassezia</i> spp., <i>A. fumigatus</i> , <i>F. solani</i>	≤0.5–8 µg/ml	Approved as topical treatment for onychomycosis
Antifolates	Dihydropteroate synthase (DHPS)	<i>A. fumigatus</i> , <i>Cryptococcus</i> spp.	4 to ≥256 µg/ml synergism with trimetoprim	Not
Antifolates	Dihydrofolate reductase (DHFR)	<i>C. albicans</i> , <i>C. glabrata</i>	0.2–1024 µg/ml	Not
Cyclosporine A and tacrolimus	Calcineurin	<i>C. albicans</i> , <i>Cryptococcus</i> spp., <i>Aspergillus</i> spp., <i>Sporothrix</i> spp., <i>Trichosporon</i> spp., <i>Malassezia</i> spp., Mucorales	1 to > 64 µg/ml synergism with azoles, amphotericin B and caspofungin	Not

(Continued)

Table 1 Continued

Compounds	Molecular target	Target species	MIC values	In vivo
<i>Geldanamycin</i>	Hsp90	<i>Candida</i> spp., <i>Aspergillus</i> spp., <i>Mucor</i> spp., <i>Fusarium</i> spp., <i>Paecilomyces</i> spp.	2 to > 16 µg/ml synergism with azoles and echinocandins	Candidiasis and aspergillosis (<i>Galleria mellonella</i> and murine)
<i>Efungumab</i> or <i>Mycograb</i>	Hsp90	<i>Candida</i> spp.	128–256 µg/ml synergism with fluconazole, caspofungin, and amphotericin B	Candidiasis (murine)
<i>Miltefosine</i>	Not fully elucidated	<i>Candida</i> spp., <i>Cryptococcus</i> spp., <i>Paracoccidioides</i> spp., <i>H. capsulatum</i> , <i>C. posadasii</i> , <i>Sporothrix</i> spp., <i>Aspergillus</i> spp., <i>F. solani</i> , <i>Scedosporium</i> spp., <i>Pythium</i> spp., and Dermatophytes	0.12 to > 64 µg/ml	Candidiasis and cryptococcosis (<i>Galleria mellonella</i> and murine)
<i>OIPC</i>	Not fully elucidated	<i>C. albicans</i> , <i>Aspergillus</i> spp.	1–4 µg/ml	Candidiasis (murine)
<i>Sertraline</i>	Not fully elucidated	<i>Cryptococcus</i> spp., <i>Candida</i> spp., <i>S. schenckii</i> , <i>T. asahii</i>	2–8 µg/ml synergism with azoles and amphotericin B	Cryptococcosis (murine)
<i>Tamoxifen</i>	Not fully elucidated	<i>S. cerevisiae</i> , <i>C. albicans</i> , <i>C. neoformans</i>	4–64 µg/ml	Candidiasis and cryptococcosis (murine)
<i>Verapamil</i>	Calcium channel	<i>C. albicans</i> , <i>A. fumigatus</i> , <i>F. solani</i> , <i>Scedosporium</i> spp., <i>Trichoderma</i> spp., <i>Rhizopus</i> spp.	853–2731 µg/ml synergism with azoles and polyenes	Aspergillosis and gastrointestinal-colonization by <i>C. albicans</i> (murine)
<i>Benzimidazoles</i>	β-tubulin	<i>C. neoformans</i>	0.095–0.125 µg/ml	Cryptococcosis (murine)

Note: GPI: glycosylphosphatidylinositol; SQS: squalene synthase; 24-SMT: Sterol C24-methyltransferase; Ipc1: inositol phosphorylceramide 1; GlcCer: glucosylceramide; Hsp90: Heat shock protein 90; BHBm: N'-(3-bromo-2-hydroxybenzylidene) – 2-methylbenzohydrazide; DO: 3-bromo-N'-(3-bromo-4-hydroxybenzylidene) benzohydrazide; OIPC: Oleylphosphocholine.

activity seems to be essential in *C. albicans* (Carman *et al.*, 2008) and is required for virulence in *C. neoformans* (Hu *et al.*, 2008). The inhibition of fungal ACs results in autophagy, decreased histone acetylation, and loss of cellular integrity, while it also down-regulates host chaperone proteins that reduce the immune response (Koselny *et al.*, 2016b; Kushwaha *et al.*, 2017; Mourad and Perfect, 2018). AR-12 has a broad spectrum of activity on planktonic cells of *Candida* spp., *Cryptococcus neoformans*, *Fusarium* spp., *Mucor*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, and *C. immitis* (Baxter *et al.*, 2011; Koselny *et al.*, 2016a,b). AR-12 also demonstrated antibiofilm effects on *C. albicans* biofilms (Baxter *et al.*, 2011) and, in combination with fluconazole, showed synergistic and fungicidal effects on *C. neoformans* *in vitro* (Chabrier-Roselló *et al.*, 2013). In a murine model of disseminated cryptococcosis, the combination of AR-12 and fluconazole reduced the fungal burden in the brain, which was not observed when the drugs were used alone (Koselny *et al.*, 2016a). In addition, safety and tolerability of AR-12 were evaluated in a phase I clinical trial for its use as an anticancer agent (NCT00978523).

Ergosterol Biosynthesis

Both ergosterol and cholesterol are synthesized from acetyl-CoA via a series of enzymatic reactions that are identical between fungi and animals up to the synthesis of lanosterol, the key branching point. The azoles primarily block ergosterol synthesis by inhibiting lanosterol-14 α -demethylase (Erg11), the first primary target in the fungal membrane that is not present on the host cell membrane (Perfect, 2017). Squalene synthase (SQS) and sterol C24-methyltransferase (24-SMT) inhibitors block upstream and downstream steps of lanosterol synthesis, respectively. Despite the extensive and exciting reports highlighting the potential of SQS and 24-SMT inhibitors as promising lead compounds or antifungal drugs *in vitro*, little has been translated to *in vivo* and clinical studies.

Squalene synthase (SQS)

Known inhibitors of human SQS, a target for hypercholesterolemia and atherosclerosis therapies, include zaragozic acids, quinuclidines, benzoxazepines and substituted morpholines (Kourounakis *et al.*, 2011). Quinuclidine-based SQS inhibitors, such as E5700 and ER-119884, were originally developed by Eisai (Tokyo, Japan) as cholesterol- and triglyceride-lowering agents for human diseases, but later demonstrated important antiprotozoal activities *in vitro* and against acute Chagas disease in a murine model (Urbina *et al.*, 2004). Both E5700 and ER-119884 inhibited growth and altered the lipid profile and ultrastructure of the multidrug-resistant *C. tropicalis* strain, and, thus, could act as leads for the development of new compounds against the multidrug-resistant *Candida* species (Ishida *et al.*, 2011b). Similarly, an arylquinuclidine derivative (WSP1267) effectively inhibited the *in vitro* growth of a collection of *Candida* clinical isolates, including several non-*albicans* and azole-resistant strains (Ishida *et al.*, 2011a). Using a different approach, Song and colleagues screened a library of 744 compounds against *Aspergillus flavus* SQS, and the best inhibitor, celastrol, was found to be a noncompetitive inhibitor of *Aspergillus* SQS with inhibitory effects on *A. fumigatus*, the main causative agent of invasive aspergillosis in humans (Song *et al.*, 2019).

Sterol methyltransferase (SMT)

Azasterols 20-piperidin-2-yl-5 α -pregnan-3 β -20(R)-diol (AZA) and 24(R,S),25-epiminolanosterol (EIL) are steroid compounds and are known inhibitors of 24-SMT in fungi (Song and Nes, 2007). EIL antifungal activity was described for *C. neoformans* and *C. albicans*, with a potency comparable to itraconazole (Ishida *et al.*, 2009; Nes *et al.*, 2009). AZA also showed potent activity against *C. albicans* (Ishida *et al.*, 2009) and *Pneumocystis carinii* (Urbina *et al.*, 1997); interestingly enough, AZA showed the highest potency against the dimorphic fungus *Paracoccidioides brasiliensis* (Visbal *et al.*, 2003). Sulfur-containing sterols, such as 25-thialanosterol and 25-thialanosterol iodide, also demonstrated *in vitro* disruption of ergosterol biosynthesis in *C. albicans* via inhibition of 24-SMT (Kanagasabai *et al.*, 2004; Leaver, 2018). Additionally, α -Bisabolol, a natural phenylpropanoid found in *Matricaria recutita* and *Plinia cerrocampanensis* essential oils, impairs the growth of *A. fumigatus* via inhibition of microsomal 24-SMT (Jahanshiri *et al.*, 2017). Abafungin is the first member of a novel class of synthetic antifungal compounds, the arylguanidines, and presents potent *in vitro* antifungal activity against several medically important fungi, including dermatophytes, *Candida* sp. and *Aspergillus* sp. (Borelli *et al.*, 2008). Preliminary studies suggested that abafungin inhibits transmethylation at the C-24 position of the sterol side chain, which is catalyzed by 24-SMT, while a secondary mechanism involves a direct effect on the fungal cell membrane (Borelli *et al.*, 2008). Finally, the 24-SMT inhibitor 22-hydrazone-imidazolin-2-yl-cholesterol-5-ene-3 β -ol (H3) impaired fungal growth and sterol composition of the dimorphic fungi *Sporothrix schenckii* and *Sporothrix brasiliensis*, confirming 24-SMT as a promising target for novel antifungal therapies, including emergent species, like *Sporothrix* spp. (Borba-Santos *et al.*, 2016).

Sphingolipid Biosynthesis

Sphingolipids are important in cellular metabolism and can have a relevant role in the regulation of fungal virulence. Therefore, blocking the synthesis and/or function of specific fungal sphingolipids is an attractive area for the development of new antifungals. Although the most frequent sphingolipid in mammalian cells is sphingomyelin, there are two main groups described in fungal cells: inositol phosphorylceramide (IPC) and hexosylceramides, such as glucosylceramide (GlcCer); therefore, inhibitors of IPC and GlcCer synthesis could potentially be developed into new antifungal drugs (Rollin-Pinheiro *et al.*, 2016).

Inositol phosphorylceramide synthase (IPCs)

Aureobasidin A (AbA) is a natural compound that inhibits inositol–phosphoryl ceramide synthase 1 (IPCs1), particularly in yeasts such as *C. albicans*, *S. cerevisiae* and *C. neoformans* (Aeed *et al.*, 2009). In addition to decreased IPC production, AbA treatment results in the accumulation of ceramide to a toxic level (Cerantola *et al.*, 2009) and, in *C. albicans*, AbA impairs germ tube elongation and affects *in vitro* biofilm formation (Tan and Tay, 2013). Despite having good activity against yeasts, AbA showed reduced activity against molds like *Aspergillus* sp., but structural modifications aiming to broaden its spectrum of activity are very promising. A recent agreement between AureoGen, a small pharmaceutical company involved in the research and development of AbA, and Merck may advance the development and potential commercialization of the first fungal IPCs1 inhibitor (Rollin-Pinheiro *et al.*, 2016).

GlcCer synthase

Natural products have been shown to target GlcCer directly to affect fungal growth. Defensins from plants and insects, such as RsAFP2 (*Raphanus sativus* antifungal protein 2), are active against *C. albicans* strains; moreover, *C. glabrata* (known to lack GlcCer) are resistant to RsAFP2, suggesting that this could be the target of defensins (Tavares *et al.*, 2008). RsAFP2 directly impairs *C. albicans* yeast–hyphae transition, a crucial step for pathogenesis, and induces the accumulation of ceramides, which leads to apoptosis (Thevisen *et al.*, 2012). Two synthetic compounds that might potentially target GlcCer, N'-(3-bromo-2-hydroxybenzylidene)-2-methylbenzohydrazide (BHBM) and 3-bromo-N'-(3-bromo-4-hydroxybenzylidene)benzohydrazide (DO), showed *in vitro* and *in vivo* antifungal activity against most of the medically important fungi, including *C. neoformans*, *Candida* spp., *Pneumocystis* sp., *A. fumigatus* and *H. capsulatum*. Besides having broad antifungal activity, BHBM and DO were also well tolerated by animals and were additive to current antifungals (Mor *et al.*, 2015).

Efflux Pump

Many fungal species acquire azole resistance via overexpression of efflux pumps; it is the most common antifungal resistance mechanism (Cannon *et al.*, 2009; Zavrel and White, 2015). Two classes of efflux pumps have been found in fungi: ATP-binding cassette (ABC) proteins and major facilitator superfamily (MFS) pumps. ABC proteins constitute a large class of drug efflux pumps that use ATP hydrolysis to translocate compounds across cell membranes (Del Sorbo *et al.*, 2000). In this context, one possible option to tackle resistance could be the use of transporter inhibitors, especially in combination with antifungals.

Milbemycins (A3 and A4) and their derivatives, known as ABC transporter inhibitors, are products of fermentation made by *Streptomyces* species (Kumar and Jha, 2017). Milbemycins showed intrinsic antifungal activity and, importantly, they caused a reduction in the MIC values of fluconazole and voriconazole for *C. albicans* and *C. glabrata* (Silva *et al.*, 2013; Walker *et al.*, 2014). In an invasive candidiasis murine model, treatment with milbemycin A3/A4 decreased the fungal burden in the infected tissues and acted synergistically with fluconazole (Silva *et al.*, 2013).

Unnarmicins (A and C) were isolated from the marine bacterium *Photobacterium* (Tanabe *et al.*, 2007; Oku *et al.*, 2008), and both increased the susceptibility of the ABC transporter-overexpressing *S. cerevisiae* strain to fluconazole; most importantly, these compounds were also able to strongly sensitize azole-resistant *C. albicans* clinical isolates (Tanabe *et al.*, 2007).

In addition, organic compounds containing tellurium reduced *S. cerevisiae* growth by disrupting its ATPase function (Chan *et al.*, 2007; Reis de Sá *et al.*, 2014). Moreover, these compounds reversed the resistance phenotype to fluconazole in ABC transporter-overexpressing *S. cerevisiae* and *C. albicans* strains; the authors then attributed the ABC transporters as targets for these compounds (Reis de Sá *et al.*, 2014).

Proton Pump

Proton pump inhibitors, such as omeprazole, rabeprazole, lansoprazole, pantoprazole, and esomeprazole, act as agents with antifungal activity or reverse-acquired resistance to azoles (Afeltra and Verweij, 2003). These compounds inhibited *Cryptococcus* spp., *Candida* spp. and *S. cerevisiae* (Küçükaslan *et al.*, 2013; Brilhante *et al.*, 2019). Omeprazole also has an antifungal effect and is known to inhibit the fungal plasma membrane proton ATPase Pma1 of *C. albicans* and *S. cerevisiae* (Monk *et al.*, 1995; Manavathu *et al.*, 1999). Importantly, when proton pump inhibitors are combined with azole agents, a significant reduction in MIC values of both drugs is observed, suggesting a synergistic action, as seen in *A. fumigatus* (Afeltra *et al.*, 2004).

Protein Synthesis

Elongation Factor 2 (EF2)

Sordarins, such as zofimarin, BE31405, xylarin, hipoxysordarin, neosordarin, and GR135402 and derivatives, were isolated from various fungal species and are potent and selective inhibitors of translation in fungal cells, interacting with the fungal EF2 to stabilize the EF2-ribosome complex (Liang, 2008; Vicente *et al.*, 2009). *In vitro* studies demonstrated the activity of sordarins against *Candida* spp., *C. neoformans*, *P. carinii* (currently called *P. jirovecii*), and some filamentous fungi (Herreros *et al.*, 1998; Odds, 2001). *In vivo* activity was observed in murine models of candidiasis and histoplasmosis, where treatments increased animal survival and decreased the fungal

burden (Graybill *et al.*, 1999; Aviles *et al.*, 2000; Kamai *et al.*, 2005). Recently, sordarins and synthetic derivatives showed potent fungicidal and pan-fungal activities (Chakraborty *et al.*, 2016; Wu and Dockendorff, 2019; Zhang *et al.*, 2019).

Transfer RNA Synthetase

Tavaborole (AN2690), a benzoxaborole compound, exerts its antifungal activity by blocking protein synthesis and inhibiting cytoplasmic leucyl-aminoacyl transfer RNA (tRNA) synthetase (Markham, 2014). *In vitro* studies showed that tavaborole is effective for dermatophytes (Markham, 2014) and several other fungi, such as *Candida* spp., *C. neoformans*, *Malassezia* spp., *A. fumigatus* and *F. solani*, presenting a broad action spectrum (Gupta and Daigle, 2014). Clinical trials showed that tavaborole has characteristics that allow for favorable penetration into and permeation throughout the human nail plate and can be safe and effective when used topically for the treatment of toenail onychomycosis (Del Rosso and Plattner, 2014; Jinna and Finch, 2015). Tavaborole 5% solution was approved by the US FDA in July 2014 for use as a topical treatment for onychomycosis as an alternative to the conventional antifungals (Gupta and Daigle, 2014).

Folate Biosynthesis

Antifolates are chemical compounds that interfere with folate biosynthesis, an important pathway for the biosynthesis of purines, pyrimidines and several amino acids (Visentin *et al.*, 2012). Two important steps in folate biosynthesis involve dihydropteroate synthase (DHPS) and dihydrofolate reductase (DHFR).

Dihydropteroate Synthase (DHPS)

DHPS catalyzes the conversion of PABA (para-aminobenzoate) to dihydropteroate (Minato *et al.*, 2015), and the main DHPS inhibitors are sulfonamides, a class of synthetic molecules that act as competitive inhibitors (Griffith *et al.*, 2018). The sulfonamides, such as sulfamethoxazole, sulfadiazine, sulfadoxine and others, are usually recommended to treat bacterial infections and are frequently used in combination with DHFR inhibitors due to increased resistance in monotherapy (Griffith *et al.*, 2018). Besides having antibacterial activity, DHPS inhibitors have demonstrated antifungal activity against *Trichophyton longifusus*, *Microsporum canis*, *C. albicans*, *C. glabrata*, *A. flavus*, and *F. solani* (Chohan *et al.*, 2006).

Dihydrofolate Reductase (DHFR)

DHFR catalyzes the reduction of dihydrofolate to tetrahydrofolate, an essential cofactor for the synthesis of purines, thymidine, glycine, and methionine, which affects DNA replication, repair and methylation, and its blocking mechanism presents an interesting strategy for drug discovery (Daly *et al.*, 1994; Paulsen *et al.*, 2013; Al-Rashood *et al.*, 2014; Alotaibi *et al.*, 2017). DHFR is currently targeted by methotrexate (MTX) and trimetrexate (both anticancer), trimethoprim (TMP, antibacterial), pyrimethamine (PYR, anti-protozoan) (Alotaibi *et al.*, 2017), proguanil (antimalarial) and others (Gregson and Plowe, 2005). Some of these molecules also show *in vitro* antifungal activities; PYR inhibited growth of *C. albicans*, whereas TMP and MTX were not effective alone in inhibiting *C. albicans*, but MTX in combination with azole agents led to a synergistic effect (Navarro-Martínez *et al.*, 2006; Yang *et al.*, 2019). In the last decade, researchers have developed new compounds with higher selectivity and greater affinities for DHFR in *C. albicans* and other species (Vuppala *et al.*, 2019), such as propargyl-linked antifolate derivatives (G-Dayananandan *et al.*, 2014), quinazolines (Al-Rashood *et al.*, 2014), some triazoles (Hassan *et al.*, 2013), Furo compounds, and pyrrolo pyrimidines (Cody and Schwalbe, 2006).

Although DHPS and DHFR inhibitors had reduced antifungal activity, the combination of sulfamethoxazole with trimethoprim exhibits a synergistic effect and has been used for years to treat paracoccidioidomycosis in Latin America (Shikanai-Yasuda *et al.*, 2017).

Cell Stress Regulators

Calcineurin

Calcineurin is a conserved Ca^{2+} -calmodulin-activated protein phosphatase 2B belonging to the phospho-protein phosphatase family of enzymes, and its signaling plays diverse roles in fungi in regulating stress responses, morphogenesis and pathogenesis (Juvvadi, Lamoth and Steinbach, 2014; Juvvadi *et al.*, 2017). Calcineurin is the target of immunosuppressive drugs such as cyclosporine A and tacrolimus (FK506) (Steinbach *et al.*, 2007). Many studies show that calcineurin inhibitors are effective against clinically important fungi, such as *C. albicans*, *Cryptococcus* spp., *Aspergillus* spp., *Sporothrix* spp., *Trichosporon* spp., *Malassezia* spp., and Mucorales (Stie and Fox, 2008; Shirazi and Kontoyiannis, 2013; Kubiça *et al.*, 2016; Borba-Santos *et al.*, 2017; Ianiri *et al.*, 2017). Additionally, calcineurin inhibitors have a synergistic effect with antifungal drugs, such as azoles, amphotericin B and caspofungin (Shirazi and Kontoyiannis, 2013; Kubiça *et al.*, 2016).

Heat Shock Protein 90 (Hsp90)

This chaperone regulates crucial cell responses to both cell membrane and cell wall stresses and has been extensively validated as a regulator of virulence and antifungal drug resistance (Huang *et al.*, 2019). Geldanamycin and Efungumab (Mycograb) act on Hsp90. Studies show that geldanamycin has activity on yeast and filamentous fungi in combination with azoles and echinocandins in *in vitro* and *in vivo* models (Cowen *et al.*, 2009; Zhang *et al.*, 2013; Lamoth *et al.*, 2014). Mycograb (a monoclonal antibody), when combined with fluconazole, caspofungin, and amphotericin B, has synergy against the *Candida* species *in vitro*, and in a murine model of invasive candidiasis *in vivo* (Bugli *et al.*, 2013). Moreover, the efficacy and safety of Mycograb for cryptococcal meningitis were evaluated in phase II clinical trials (NCT 00324025 and NCT00847678).

Drug Repositioning

The repositioning of drugs refers to the establishment of a new pharmacological indication for a drug that was previously approved for another purpose (Truong *et al.*, 2018), offering attractive benefits, as toxicological and pharmacokinetic profiles have been established previously, accelerating development time and avoiding substantial costs associated with costly clinical trials (Krysan, 2015; Truong *et al.*, 2018).

Miltefosine (MFS)

Initially developed as an anticancer agent and currently used in the treatment of certain breast cancer types, MFS is an alkyl phosphocholine compound that has been repurposed for the treatment of leishmaniasis (Sundar and Chakravarty, 2015). MFS has shown impressive broad-spectrum antifungal activity *in vitro*, covering most medically important fungi, including yeasts (*Candida* spp. and *Cryptococcus* spp.), dimorphic fungi (*Paracoccidioides* spp., *H. capsulatum*, *C. posadasii*, *Sporothrix* spp.), dermatophytes and several other filamentous fungi (Widmer *et al.*, 2006; Tong *et al.*, 2007; Brilhante *et al.*, 2014, 2015; Imbert *et al.*, 2014; Borba-Santos *et al.*, 2015; Compain *et al.*, 2015; Rossi *et al.*, 2017; Loreto *et al.*, 2018). MFS was effective against *Candida* spp. biofilms *in vitro* (Vila *et al.*, 2013, 2016), including the emerging multidrug-resistant species *C. auris* (Wall *et al.*, 2019), and reduced the biomass of *F. oxysporum* biofilms (Vila *et al.*, 2015b). Most importantly, MFS was effective as a topical treatment for oropharyngeal candidiasis in a murine model (Vila *et al.*, 2015a), confirming its promising application for superficial and mucosal fungal infections. However, conflicting studies demonstrated variable translation of MFS *in vivo* activity against disseminated cryptococcosis (Widmer *et al.*, 2006; Wiederhold *et al.*, 2013). Moreover, MFS reduced the fungal infection burden from *C. albicans* and *C. gattii* in the larval model of *Galleria mellonella* (Spadari *et al.*, 2019).

The mechanism of action of MFS in fungi is still unknown, but signaling to an apoptotic-like cell death via activation of metacaspase Mca1 by ROS accumulation in the mitochondria was observed in *S. cerevisiae* (Biswas *et al.*, 2014), and similar results were obtained for *C. neoformans* (Spadari *et al.*, 2018). Moreover, MFS induces other physiological effects, including increased plasma membrane permeability and melanin accumulation (Borba-Santos *et al.*, 2015; Rossi *et al.*, 2017; Spadari *et al.*, 2018).

Strategies including the synthesis of structural analogs and the development of drug delivery systems were applied to MFS to reduce its cytotoxicity. Encapsulation of MFS in alginate nanoparticles decreased toxic effects and infection in the *G. mellonella* model (Spadari *et al.*, 2019), while a few structural analogs of MFS showed enhanced *in vitro* inhibition of *C. albicans* (Vila *et al.*, 2013) and *Sporothrix* spp. (Borba-Santos *et al.*, 2016). Oleylphosphocholine (OIPC) is the most extensively explored MFS analog to date. OIPC is effective *in vitro* and *in vivo* against *C. albicans* biofilms (Holtappels *et al.*, 2017). OIPC showed excellent *in vitro* activity against *Aspergillus* spp.; however, its therapeutic efficacy in an acute mouse model for invasive aspergillosis was less convincing, and other clinically relevant animal models should be further evaluated (Paulussen *et al.*, 2015). Compared to MFS, OIPC exhibited fewer side effects when tested *in vivo* and has good oral bioavailability. Further pharmacokinetic and pharmacodynamic data will confirm OIPC as a potential candidate for clinical studies.

Sertraline

Antidepressant drugs such as sertraline showed antifungal effects alone and in combination with azoles or amphotericin B *in vitro* against *Cryptococcus* spp., *Candida* spp., *S. schenckii* and *T. asahii* (Zhai *et al.*, 2012; Cong *et al.*, 2016; Costa Silva *et al.*, 2017; Oliveira *et al.*, 2018; Villanueva-Lozano *et al.*, 2019). Additionally, sertraline efficiently reduced the fungal burden in the brain and spleen of mice infected with *C. neoformans* (Zhai *et al.*, 2012; Treviño-Rangel *et al.*, 2016). Its mechanism of action on fungi is not fully elucidated; however, a fungicidal effect which occurs by damaging the plasma and mitochondrial membranes to activate apoptotic signaling pathways was described for *Candida* spp. (Costa Silva *et al.*, 2017); inhibition of protein synthesis by sertraline was observed for *Cryptococcus* spp. (Zhai *et al.*, 2012). Currently, sertraline use is in clinical trials (phase III) for oral treatment of cryptococcal meningitis alone or in combination with AMB and FLC (NCT 01802385 and NCT 03002012).

Tamoxifen

Tamoxifen is a selective estrogen receptor modulator used in breast cancer treatments (Ngan *et al.*, 2019). Its *in vitro* antifungal activity was observed against *S. cerevisiae* (Wiseman *et al.*, 1989), *C. albicans* (Beggs, 1993; Dolan *et al.*, 2009) and *C. neoformans* (Hai *et al.*, 2019). Tamoxifen reduced the fungal burden in a murine model of disseminated candidiasis and cryptococcosis, and researchers have proposed tamoxifen as an alternative for neurocryptococcosis due its ability to cross the blood-brain barrier and accumulate in the brain at levels well above the MIC values (Morello *et al.*, 2003; Dolan *et al.*, 2009; Butts *et al.*, 2014). The antifungal activity of tamoxifen is the result of its effects on multiple physiological processes, such as membrane damage and interference with calcium homeostasis, and studies show that its activity correlates with calmodulin inhibition (Dolan *et al.*, 2009; Butts *et al.*, 2015). Clinical trial studies (phase II) are beginning to evaluate the efficacy, feasibility, and safety of tamoxifen in combination with standard therapies (amphotericin B and fluconazole) in the treatment of cryptococcal meningitis (NCT03112031).

Verapamil

A typical calcium channel blocker of the phenylalkylamine class, verapamil is widely used in the treatment of angina pectoris and hypertension (Strigun *et al.*, 2011). The *in vitro* antifungal activity of verapamil led to a significant decrease in the *C. albicans* hyphal development and the ability to adhere to a polystyrene surface (Yu *et al.*, 2014). Moreover, treatment with verapamil led to a remarkable decrease in gastrointestinal-colonizing fungal cells (Yu *et al.*, 2014). Verapamil alone, however, had poor antifungal activity (Homa *et al.*, 2017). Studies suggest that the combination of verapamil with azoles or polyenes shows synergistic effects and is a promising therapy for *C. albicans*, *A. fumigatus*, *F. solani*, *Scedosporium* spp., *Trichoderma* spp., and *Rhizopus* spp. (Krajewska-Kulak and Niczyporuk, 1993; Afeltra *et al.*, 2004; Homa *et al.*, 2017; Nazik *et al.*, 2017). Recently, the combination of verapamil with itraconazole controlled fungal infection with *A. fumigatus* in an invasive aspergillosis murine model by improving the survival rate of animals and reducing the fungal burden in the lungs (Zeng *et al.*, 2019).

Benzimidazoles

These molecules were developed primarily as anthelmintic agents for human and veterinary medicine (Cruz *et al.*, 1994). Benzimidazole drugs, such as albendazole, mebendazole, and flubendazole, have potent *in vitro* activity against *C. neoformans*, and flubendazole is effective in murine models of cryptococcal meningitis (Joffe *et al.*, 2017; Nixon *et al.*, 2018). The authors suggested that benzimidazoles inhibit fungal growth by blocking β -tubulin polymerization for microtubule formation, disrupting mitosis (Cruz *et al.*, 1994), and interfering with fungal morphology, biofilm formation, cell proliferation and intracellular parasitism (Joffe *et al.*, 2017).

Acknowledgments

Glossary

Adaptive immunity Microbe-specific, antigen-educated, mature T- and B-cells, which create long-term immunological memory with recall function, initiate cross-talk between immune components via biochemical messenger proteins known as “cytokines” and “chemokine’s,” and recruit other immune effectors to the site of host–microbe interaction.

Adjuvant Pharmacological or immunological agents which, when coadministered with the vaccines, modulates the quantum and/or kinetics of the immune response due to the vaccine.

Barrier immunity Physical impediments to the entry of a microbe into the human body. For example, the skin, external surface epithelium, and internal linings of the upper and lower respiratory, gastrointestinal, and genitourinary tracts.

Colonization A state following infection in which a microbe inhabits a niche in the host and host–microbe interaction, which is not clinically apparent, results in elimination of the microbe or transition to other states, such as disease or latency.

Commensalism A state following infection in which the outcome of host–microbe interaction results in neutral, cooperative, symbiotic, or beneficial outcomes for the host and there is no host damage.

Damage-response framework (DRF) A unifying hypothesis to account for microbial pathogenesis and infectious diseases as a function of host–microbe interaction. The DRF asserts that the relevant outcome of host–microbe interaction is damage in the host, which can stem from host factors, microbial factors, or both. All outcomes of infection can be reconciled as the amount/degree of damage stemming from host–microbe interaction. This dispenses with the need for terms to characterize microbes that assume they or impaired hosts are solely responsible the pathogenesis of infectious diseases, such as pathogen, commensal, and opportunist. The DRF considers the balance between the host response and host damage, defines disease as one possible outcome of host–microbe interaction, and recognizes that the host response may result in damage due to either an insufficient or excessive immune response. These concepts provide the rationale for immune-based therapies for microbial diseases.

Damage Impairment of normal host physiology, biology, immunity, and/or other functions that may stem from host factors, microbial factors, or both.

Effector leukocytes White blood cells that perform specific immune defense functions. Some examples are: T-lymphocytes or “T-cells,” which may be helper (T_H) or

regulatory (T_{reg}) cells bearing CD4 antigen on surface, or cytotoxic (T_C) bearing CD8 antigen; B-lymphocytes or “B-cells,” which secrete antibodies; dendritic cells (DC); natural killer (NK) cells; monocytes, which become macrophages on entering the tissues; polymorphonuclear neutrophils (PMNs), amongst others.

Exposure Point of actual contact between a host and a microbe.

Host immunity Aggregate of immune mechanisms that enable a host to resist development of damage stemming from host–microbe interaction.

Immunomodulation Aggregate of processes in which immune-reactive components of either host defense or microbe switch on, turn off, regulate, enhance or decrease the quantum of immune response and inflammation in the host.

Immunotherapy Therapies in which components of the immune system and/or microbial components are administered to reduce the amount/degree of host damage stemming from host–microbe interaction.

Immunotherapies can be active, for example, vaccines, or passive, for example, delivery of components of the immune system.

Infection Acquisition of a microbe by a host.

Infectious disease A clinical state that reflects an outcome of host–microbe interaction that arises in a susceptible host when the amount or degree of host damage reaches a clinically apparent or assessable state.

Inflammation Aggregate of biochemical messenger-mediated processes by which effector leukocytes are brought to the site of immune unrest, such as host–microbe or host–allergen interaction. Because of the natural functions of these effectors, excessive inflammation results in damage to the host tissues at the site of these interactions.

Innate immunity Broad spectrum, nonspecific, rapidly active immune defense provided by effector leukocytes (cell-mediated immunity) and circulating antibodies produced by subsets of naïve B-lymphocytes (antibody-mediated immunity). These components are capable of killing microbes via various mechanisms.

Latency/persistence A state following infection in which a microbe remains in the host in a manner that does not result in its elimination; there is no clinically apparent damage, but transition to a state of disease can occur in the setting of immune impairment and/or other processes.

Monoclonal antibody Antibodies secreted by a single B-cell. These antibodies recognize a single determinant on the eliciting antigen. Monoclonal antibodies can be isolated from polyclonal responses and/or produced by molecular engineering from single B-cells by a variety of techniques.

Opsonization A process in which microbial cells or microbe-derived materials are coated with antibodies or small protein fragments generated by the complement system. This marks the cells/materials for further action by professional phagocytes (DCs, monocyte/macrophages, PMNs) and/or cytotoxic cells.

Pathogenesis Aggregate of processes that shifts the physiological state from normal host physiology, biology, immunity, and functions to damage.

Phagocytosis and antigen presentation The process of engulfment of microbial cells/products by certain immune effectors, referred to as phagocytes. The engulfment creates a fluid-filled space ("vacuole") in which the microbes/products are trapped. Next, reactive chemical substances and/or enzymes are released in the vacuole, which kill the microbes and/or digest the products into much smaller fragments. These fragments are associated with certain membrane-bound protein structures called major histocompatibility complexes (MHCs) and presented to T- and B-cells for their education, maturation and generation of immunological memory. This process is referred to as "antigen presentation."

Polyclonal antibody response Population of antibodies secreted by different B-cells in response to an antigen. The

resultant immunoglobulin's generally recognize multiple determinants of eliciting antigen.

Trained immunity A relatively new concept in which NK cells and monocyte/macrophages may undergo extra-chromosomal or epigenetic reprogramming to generate short-term immune memory.

Vaccine A single or a combination of antigen(s) which, when administered to a host induce/s an immune response to the administered component/s that results in microbe-specific immunity as well as immunological memory.

Administration of a vaccine, known as "vaccination" or "immunization," elicits immune responses in the host that prevent the development of disease. Active vaccination is used to induce immunity prior to exposure or infection with a microbe. Passive vaccination is used to provide exogenous preformed immunity to treat or prevent disease. Passive and active vaccination each augment the ability of the host to limit damage stemming from the host-microbe interaction.

Virulence factors Microbial factors and/or components that confer or enhance a microbe's capacity to cause damage in a host. Many such factors allow the microbe to evade host defenses, thrive in inhospitable intracellular environments, and be invulnerable to cytotoxic host immune mechanisms.

Introductory Concepts

Host-Microbe Interaction, Infection, Disease, Damage

The term "infectious disease" refers to a clinical state that occurs as a result of infection with a microbe when the amount/degree of damage to host tissues resulting from a host-microbe interaction becomes clinically apparent and/or assessable. However, an infectious disease does not represent necessarily a single outcome, but is rather one possible outcome of a host-microbe interaction (Pirofski and Casadevall, 2002). Just as a host exhibits (an) immune response to a microbe, microbes exist in hosts in different states. The first step in the pathogenesis of an infectious disease is exposure, which is the (first) point of actual contact (or the possible risk of contact) between a host and a microbe. Infection signals the acquisition of a microbe by a host. There are multiple portals by which a microbe can infect a host, including respiratory, gastrointestinal, cutaneous, and hematogenous sites. However, not all states of microbial existence within a host lead to a clinically symptomatic or detectable/assessable state; thus neither exposure nor infection alone is sufficient to predict the occurrence of the state of disease. The states that are asymptomatic include commensalism, colonization, and latency, which differ from one another only by the amount or degree of host damage that results from the host-microbe interaction. However, these states can transition to disease in the setting of host immune impairment and defects, such as a breakdown in barrier immunity, insufficient and excessive immune responses, and physiological immune impairments that occur throughout the lifespan of the host. "Successful" host responses can lead to the elimination of a microbe, a process that antimicrobial therapy also seeks to accomplish. This theory of infectious disease/microbial pathogenesis was put forth as the damage-response framework (DRF) by Casadevall and Pirofski (1999, 2003b) and Pirofski and Casadevall (2002, 2008).

Although quantification of disease as a function of host damage is a central tenet of the DRF, measureable indices of damage remain relatively limited to radiographic findings, perturbations in leukocyte counts and other hematologic indices, and alterations in temperature and physiological state as measured by blood pressure and hemodynamic parameters. At present, measures of inflammation apart from fever and blood counts are not available clinically. Nonetheless, the recognition that infectious diseases reflect an outcome of host-microbe interactions has led to efforts to characterize the host response to a microbe as a prelude to designing newer therapeutic modalities, including immune-based therapies. Such therapies, known as "immunotherapy," employ active immunization with microbial components, and/or passive administration of host immune system components to reduce host damage stemming from host-microbe interaction. This chapter will focus on the application of this modality to management of medical mycoses. Notably, immunotherapy has been a mainstay of treatment for cancer for some time (Raval *et al.*, 2014). While we have done our best to comprehensively review this topic, we apologize in advance for any and all omissions readers might identify.

Host–Fungal Interaction and Virulence Factors

The outcome of fungal interaction with the host determines the state of the fungus in the host (Pirofski and Casadevall, 2015). Therefore, consideration of immunotherapy for fungal diseases must incorporate the unique challenges that fungi pose to host immunity (Casadevall and Pirofski, 2012). The ability of some fungal organisms to cause disease can be a function of certain structural and secreted components, often called “virulence factors.” Many of these factors enable the fungus to evade host defenses, thus facilitating its ability to live and disseminate in a host. The main structural component that impacts the latter is the fungal cell wall. Composed of complex polysaccharides (e.g., chitin, α - and β -glucans, etc.), lipids (such as ergosterol) and glycoproteins, the cell wall provides a structural and functional barrier that protects fungal cells from host immune-mediated damage and osmotic lysis. While the cell wall is a crucial component of all fungi, cell walls of the yeasts *Cryptococcus neoformans* and *Cryptococcus gattii* are uniquely further protected by a complex polysaccharide capsule, a significant virulence factor with immunomodulatory properties (O’Meara and Alspaugh, 2012). Microscopic asexual spores (“conidia”) of filamentous fungal (“mold”) organisms are ubiquitous and covered with a tough cell wall that protects them against both environmental and host immune challenges. For instance, the hyphae (aerial structures) and conidia of many molds contain highly hydrophobic surface proteins called hydrophobins (Bayry *et al.*, 2012) that protect conidia from immune-mediated damage, such as for *Aspergillus fumigatus* (Rambach *et al.*, 2015). In turn, conidial interaction with the host immune system can result in allergic and other inflammatory states. A number of medically important fungi, for example, species of *Candida*, *Histoplasma*, *Coccidioides*, *Paracoccidioides*, *Blastomyces*, and *Sporothrix*, exhibit dimorphism, whereby they exist in either a hyphal or a yeast/yeast-like state, with each state producing unique virulence properties. In addition, many fungi produce toxic secondary metabolites (“mycotoxins” such as gliotoxin, aflatoxin, fumonisin, etc.) that are capable of causing disease via carcinogenicity, immunosuppression, allergy, and/or metabolic derangement (Bennett and Klich, 2003).

Management of Fungal Diseases

Current antifungal chemotherapy

The current foundation of antifungal therapy consists of different classes of systemic and topical agents, including polyene macrolides, triazoles, echinocandins, a pyrimidine nucleoside analog, and other inhibitors of fungal DNA/RNA or protein synthesis. Antifungals in clinical use are safe and reasonably well tolerated. Although they can lead to fungal elimination in the setting of intact immunity, many patients with fungal diseases have varying degrees of immune impairment, a context in which fungal elimination is notoriously difficult to achieve. In addition, the use of antifungal agents is subject to drug–drug interactions, narrow activity spectrum, variable pharmacokinetics/pharmacodynamics, inherent or acquired resistance to the agent, and inadequate clearance of the fungal burden from tissues or organs (Olson *et al.*, 2012; Autmizguine *et al.*, 2014). Limitations in the use and/or efficacy of antifungal chemotherapy underscore the importance of efforts to develop immunotherapeutic approaches to prevent and treat fungal diseases.

Rationale for immunotherapy

Immunotherapy can offer adjunctive, preventative, and/or therapeutic options. This concept is bolstered by the fact that even when antifungal therapies are effective, successful management often involves engagement of host immunity. Following direct fungicidal and/or fungistatic action of an antifungal agent, the host immune system takes over further fungal elimination and scavenging of dead fungi and toxic byproducts. This process employs inflammatory mediators (cytokines and chemokines), released by innate immune cells either in response to the fungal pathogen per se, or via the immunomodulatory effect of antifungal agents (Olson *et al.*, 2012). Therefore, control of host damage, ranging from fungus-mediated damage to damage stemming from the host response, is necessary for successful management of fungal diseases.

Host immunity and antifungal defense

Host immunity represents the sum total of a multitude of immune mechanisms that enable the host to resist the development of fungal and other microbial diseases, including (1) barrier immunity, (2) specialized immune cells (cell-mediated immunity, “CMI”) in the blood and other organs, and (3) antibodies and other proteins (humoral/antibody-mediated immunity, “AMI”), produced by these cells. In the following sections, these mechanisms are discussed in the specific context of antifungal defenses.

The first line of defense is intact “barrier immunity.” These barriers, which include the skin, external and internal epithelial surfaces (including those lining the interiors of the upper and lower respiratory, gastrointestinal, and genitourinary tracts), limit/control/impair fungal invasion of the blood, brain, and other tissues (Borghi *et al.*, 2014; Dühring *et al.*, 2015). Upon breaching this first line, fungi (yeast or mold) encounter cellular components of “innate immunity,” nonspecific effector leukocytes, such as polymorphonuclear neutrophils (PMNs) and mononuclear (monocyte/macrophage, and dendritic cells/DC) phagocytes as well as circulating natural killer lymphocytes (“NK cells”) and certain subsets of naïve B-lymphocytes (“B-cells”) (Drummond *et al.*, 2014). The phagocytes engulf (“phagocytose”) and kill fungi via enzymatic lysis (Sorrell and Chen, 2009; DeLeon-Rodríguez and Casadevall, 2016). NK cells can kill fungi directly or via destruction of immune cells with internalized fungi (Djeu *et al.*, 1988; Levitz and Dupont, 1993; Murphy *et al.*, 1993; Park *et al.*, 2009; Bouzani *et al.*, 2011; Schmidt *et al.*, 2011). Additionally, NK cells and monocyte/macrophages have recently been implicated in short-term innate immune memory (referred to as “trained

immunity”) via epigenetic reprogramming independent of other effectors (Netea, 2013), which helps mount a resistance to disease/damage caused by lethal systemic fungal infections.

Fungal fragments resulting from intra- or extracellular lysis, as well as secreted fungal materials, serve as determinants for antigen-presenting cells (APCs), such as primarily macrophages, DCs, and to a lesser extent, two subsets of B-cells (B1 and Marginal Zone/MZ B-cells) (Zhong *et al.*, 2007; Hohl *et al.*, 2009; Ersland *et al.*, 2010; Drummond *et al.*, 2014; Huston *et al.*, 2016). APCs educate two important cellular components, the follicular subset of B-cells (“B2 B-cells”) and T-lymphocytes (“T-cells”), thereby bridging nonspecific, rapidly active innate immunity and fungus-specific “adaptive immunity.” Adaptive immunity consists of antigen-educated, fungus-specific, mature T- and B-cells, which create immunological memory as well as various CMI effectors that are recruited to areas of host–fungus interaction (in aggregate, “inflammation”). Adaptive responses are particularly essential to deal with fungi, many of which have the capacity for facultative intracellular survival and live dormant within phagocytes and tissues (Sebghati *et al.*, 2000; Coelho *et al.*, 2014). Effector T-cells involved in antifungal immunity are primarily of three types, namely, (1) surface CD4 glycoprotein-bearing ($CD4^+$) T-helper (T_H) cells, which play a crucial role in maturation of antigen-educated B-cells into antibody-secreting plasma cells and memory B-cells, and activation of cytotoxic T-cells (T_C) and macrophages; (2) surface CD8 glycoprotein-bearing ($CD8^+$) T_C or “Killer T” cells, with the ability to directly kill fungal cells and fungus-infested host cells as well as generate long-term immune memory (van de Veerdonk and Netea, 2010; Nanjappa *et al.*, 2012; Verma *et al.*, 2014; Gibson and Johnston, 2015); and (3) a subset of $CD4^+$ T-cells with immune-suppressive regulatory functions (“ T_{reg} ” cells). Of note, in the context of the DRF, T_H1 and T_H17 cells mediate the induction of inflammation (and, consequently, collateral tissue damage) in response to fungi, whereas T_{reg} cells are responsible for the modulation of excessive inflammation and maintenance of peripheral tolerance; interestingly, B1 and B2 B-cells work reciprocally in promoting the differentiation of T-cells into T_H or T_{reg} lineages (Zhong *et al.*, 2007).

Central to host defense against fungi are secreted molecules released by CMI effector cells (Roy and Klein, 2012; Mueller-Loebnitz *et al.*, 2013; Rohatgi and Pirofski, 2015). These include: (1) chemical messengers (proteins “cytokines” and “chemokines”) and other signaling molecules with wide-ranging mediatory and modulatory actions, for example, the immunomodulatory pro- (such as: interferon/IFN- γ , tumor necrosis factor/TNF- α , and interleukin/IL-17/22) and anti-inflammatory (such as: IL-4, IL-10; transforming growth factor/TGF- β) cytokines important in antifungal defense (Datta *et al.*, 2008; Wüthrich *et al.*, 2012; Mueller-Loebnitz *et al.*, 2013; Lauvau *et al.*, 2015; Rohatgi and Pirofski, 2015; Trautwein-Weidner *et al.*, 2015), (2) proteins with cytotoxic functions (such as: perforins, granzyme, granulysins, α - and β -defensins, etc.) (Schmidt *et al.*, 2011; Zhang and Gallo, 2016), and (3) members of the complement system, an innate defense system whose activation leads to cascading biochemical reactions generating small proteins which help kill fungi by direct cytotoxic actions or indirectly by coating the fungal cells (or fungal materials), thereby marking them (a process called “opsonization”) for action by phagocytes or NK cells. In addition, antibodies, the principal component of AMI, are immunoglobulin proteins secreted by both naïve and antigen-educated B-cells, with or without help from $CD4^+$ T-cells. AMI is significant and important in host defense and resolution of fungal infections. High-affinity antibodies elicited by mature B-cells bind specifically to antigens on the surface of, or secreted by, fungal cells, thereby triggering a number of cellular and humoral mechanisms that lead to fungal elimination (Rodrigues *et al.*, 2007; Casadevall and Pirofski, 2012; Wüthrich *et al.*, 2012; Verma *et al.*, 2014; Rohatgi and Pirofski, 2015). Functions of AMI include: (1) promotion of phagocytosis (“antibody-dependent cellular phagocytosis”) and killing by other effectors (“antibody-dependent cell-mediated cytotoxicity”/ADCC), (2) direct killing of fungal cells via complement-mediated membrane damage, (3) clearance of fungal products, (4) immunomodulation, and (5) modification of fungal metabolism/gene expression (Casadevall and Pirofski, 2005). In addition, low-affinity, naturally occurring antibodies secreted by naïve and innate-like B1 and MZ B-cells without prior antigenic stimulation that bind evolutionarily conserved microbial determinants, for example, β -glucans, likely enhance innate antifungal immunity (Panda and Ding, 2015; Rohatgi and Pirofski, 2015).

Most fungal infections do not result in disease in normal hosts with normal immunity. The state of host immunity, which ranges from immunocompetent (when immune defenses are active and appropriate) at one end of the spectrum to immunocompromised (when immune defenses are insufficient or inappropriate) on the other largely determines host susceptibility to fungal diseases. It is important to note that a variety of conditions and/or therapies, including HIV infection/AIDS, cancer, immunosuppressive chemotherapy for treatment of cancer and inflammatory diseases, biological response modifiers for inflammatory diseases, hematological or solid organ transplantation, disruption of normal skin and/or mucosal barrier immunity due to surgery, burns, and in-dwelling catheters impair immunity and render patients vulnerable to a wide array of microbes that do not generally cause disease in people with intact immunity (Pirofski and Casadevall, 2015). These microbes include fungi, such as *C. neoformans*, *Candida albicans*, *Histoplasma capsulatum*, *Aspergillus*, *Pneumocystis* and *Trichosporon* species, *Zygomycetes*, among others (Badiie and Hashemizadeh, 2014). However, it must also be noted that fungal diseases also occur in immunocompetent people (Casadevall and Pirofski, 1999, 2007a). Colonization of the nasal cavity by filamentous fungi (*Aspergillus*, dematiaceous fungi, hyaline molds, *Mucor*, etc.) may lead to sinonasal tract diseases in healthy individuals (Casadevall and Pirofski, 1999; Callejas and Douglas, 2013). *H. capsulatum*, which causes disseminated histoplasmosis in immunocompromised patients, may lead to chronic granuloma formation and fibrosing mediastinitis in apparently normal individuals with a strong immune response (Casadevall and Pirofski, 1999). *C. gattii* can cause pulmonary and central nervous system disease in the setting of normal or compromised immunity (Franco-Paredes *et al.*, 2015). Thus fungal diseases cannot be defined independently of the immune status of the host, reinforcing a central tenet of the DRF, namely, that infectious diseases can only occur in a susceptible host, providing a rationale for the use of immunotherapy for fungal diseases (Pirofski and Casadevall, 2008).

Antifungal Immunotherapy

The idea behind antifungal immunotherapy is to augment the host immune response to fungi. While in some instances it might recapitulate the “normal”/natural immune response, in others it might leverage the ability of mediators that are not part of the normal/natural response to limit/eliminate the fungus and/or damage stemming from host–fungus interaction. Many of the foregoing immune mechanisms hold promise for immunotherapeutic applications. On the basis of their impact on the host response, immunotherapeutic modalities can be divided into two main categories: active and passive.

Active Immunotherapeutic Modalities

“Active” immunotherapy is an exogenously delivered modality designed to stimulate a host immune response to the antigen/s that are administered. Vaccines are the main type of active immunotherapy. Active vaccination induces a specific response that provides the host with a preexisting immune armamentarium to the relevant microbe as well as immunological memory that makes it possible for the host to respond again in the future. Currently licensed vaccines that elicit microbe-specific immunity are composed of inactivated viruses (e.g., influenza), live-attenuated viruses (e.g., measles, mumps, rubella, varicella), or a component of a virus or bacteria (e.g., hepatitis B surface antigen, toxoids, capsular polysaccharides). In theory, vaccines can also elicit nonspecific immunity via immunization with a cross-reactive antigen present on multiple microbes (Casadevall and Pirofski, 2003a). Functionally, antimicrobial vaccines are primarily prophylactic, with the goal of helping the host develop immunity to microbial infections if/when exposure occurs. Although some antiviral vaccines, for example, rabies, can be used therapeutically very soon after exposure, current vaccines for other infectious diseases are not used in this mode. Of note, the concept of therapeutic vaccines has increasingly been leveraged for treatment of cancer (Melero *et al.*, 2014). Given that many fungal diseases occur long after infection and stem from an immune breakdown in a latent state (“reactivation”), therapeutic vaccines could hold promise for prevention and/or management of reactivated fungal infections.

The benefit of active vaccination is that it induces enduring immunity. On the other hand, its reliance on the host’s ability to develop an immune response limits its utility in the setting of impaired immunity. One additional concern is that a beneficial immune response can take time to develop, since multiple rounds of vaccination might be needed for sufficient immunity to develop. Nonetheless, despite being less immunogenic, most current vaccines are effective in patients with impaired immunity, such as those with HIV, hematologic malignancies, and on corticosteroid therapy (Nanjappa *et al.*, 2012); also, see review in Spellberg (2011). In this regard, adjuvants (such as CpG oligodeoxynucleotides/ODN) and immunomodulators, capable of enhancing the immunogenicity of the vaccines, hold further promise for immunocompromised patients (Spellberg, 2011).

Fungal vaccines

At present, there are no licensed vaccines for fungal diseases. Nonetheless, there are ample data to suggest that vaccines eliciting AMI and/or CMI could provide a rational, effective approach to preventing fungal disease. As noted above, the multitude of independent, overlapping and/or redundant mechanisms that constitute antifungal immunity offer the promise of protection via vaccines even in the setting of certain types of immune impairment (Spellberg, 2011; Iannitti *et al.*, 2012; Nanjappa *et al.*, 2012; Verma *et al.*, 2014). In this discussion, vaccines that elicit AMI will be considered first. AMI is the main mediator of protection for all currently licensed vaccines and extensive preclinical data show that AMI can enhance host resistance to a number of fungi, including *Candida* spp. and *C. neoformans*. In fact, the rationale for these vaccines is partly derived from the observation that specific antibodies develop in course of the normal response to these yeasts (see discussions in Torosantucci *et al.*, 2009; Sandini *et al.*, 2011; Datta and Subramaniam, 2014; Rohatgi and Pirofski, 2015). In addition, many preclinical studies provide strong evidence that certain conserved determinants can generate cross-reactive antibodies with a broad spectrum of activity against numerous medically relevant fungi, and vaccines which elicit antibody responses to specific and cross-reactive fungal antigens mediate protection in animal models. Several examples are discussed below.

One well-characterized, antigenic determinant that elicits AMI is the capsular polysaccharide (glucuronoxylomannan/GXM) of *C. neoformans* (Maitta *et al.*, 2004a; Datta *et al.*, 2008). A conjugate vaccine consisting of tetanus toxoid and GXM was protective against *C. neoformans* challenge in mice (Devi, 1996). Given that this GXM conjugate elicited antibodies with both protective and non-protective functions (Mukherjee *et al.*, 1995) and that capsular polysaccharides are often poorly immunogenic even when conjugated to protein carriers, peptide mimotopes of GXM that focus the antibody response on determinant(s) that elicit protective antibodies were investigated as a vaccine target for *C. neoformans* (see review in Pirofski, 2001). Indeed, a peptide mimotope-conjugate vaccine (tetanus/diphtheria toxoid conjugated to a peptide epitope mimicking a GXM determinant recognized by a protective human GXM monoclonal antibody) elicited GXM-reactive antibodies that were protective against cryptococcal challenge in mice (Maitta *et al.*, 2004b; Datta *et al.*, 2008). However, not all GXM mimotopes elicit a protective antibody response (Valadon *et al.*, 1996). Like GXM, *Candida* cell wall components β -(1,2)-mannobiose [β (Man)₂] and -triose [β (Man)₃] are poorly immunogenic by themselves; however, when conjugated to certain synthetic T-cell epitope peptides expressed during human candidiasis, β -mannotriose elicited complement-fixing antibodies that protect against disseminated and vulvovaginal candidiasis in mouse models (Xin *et al.*, 2008). Interestingly, different antigens from the same fungus can elicit different types of immunity. For example, for the dimorphic fungus *Sporothrix schenckii*, the yeast form and its exoantigens induce a T_H1/T_H17 response that is protective in mice, whereas cell wall derived-*S. schenckii* glycoprotein antigens elicit antibodies that protect against

S. schenckii and *Sporothrix brasiliensis* strains by enhancing effector cell fungal opsonization, induction of IL-12 and IFN γ , and inhibition of yeast adhesion to fibroblasts (Portuondo *et al.*, 2016).

In the context of AMI-eliciting antigens, an important example is a vaccine candidate based on a recombinant secretory aspartyl proteinase (Sap2) of *C. albicans*. This vaccine, designed primarily for therapeutic use in recurrent vulvovaginal candidiasis, exhibited a strong and encouraging outcome in a Phase 1 clinical trial (De Bernardis *et al.*, 2015). The Sap2 enzyme, despite its adhesin-like functions and ability to digest host immunity-associated proteins, has minimal immunogenicity in *Candida*-colonized subjects, and the vaccine (from Pevion Biotech, Switzerland), delivered via virosomes (viral envelopes carrying the vaccine antigen) appears to confer protection by driving the generation of adequate levels of Sap-neutralizing antibodies in both mouse models and humans (De Bernardis *et al.*, 1997, 1999, 2015; Sandini *et al.*, 2011).

With respect to vaccine antigens that elicit cross-reactive antibodies, *C. neoformans* melanin elicits antibodies that prevent growth of phylogenetically distant melanin-bearing fungi, including the yeast, *C. neoformans* and the mold *Fonsecaea pedrosoi* (Rosas *et al.*, 2001; Alviano *et al.*, 2004), and may also protect against *Paracoccidioides brasiliensis* and other melanogenic fungi (Casadevall and Pirofski, 2007b). Other determinants common between *C. neoformans* and *F. pedrosoi* are glucosylceramides, which are glycosylated sphingolipids that are part of the fungal plasma membrane and cell wall. These determinants elicit antifungal antibodies that inhibit the growth of fungi in vitro and protect mice against lethal challenge models (Nimrichter *et al.*, 2004; Rodrigues *et al.*, 2007). Surface mannans of *C. albicans* or the capsular galactoglucoylomannan of *Cryptococcus laurentii* elicit cross-reacting antibodies capable of inhibiting growth of a variety of *Candida* and cryptococcal species (Machova *et al.*, 2015). The exopolysaccharide of the fungus *Curvularia brachyspora* (chemically, mostly galactomannan) elicits antibodies that cross react with glucogalactomannan and $\beta(1,3)$ -glucan exopolysaccharides from, respectively, *Aspergillus terreus* and *Paecilomyces variotii* (Menolli *et al.*, 2014). A well-known example of a cross-reactive fungal determinant is the cell wall component laminarin/ $\beta(1,3)$ -glucan, which is common to the phylogenetically disparate fungi *Candida*, *Aspergillus*, and *C. neoformans*. A glycoconjugate (laminarin conjugated to diphtheria toxoid) vaccine elicits protective antibodies in murine models against lethal challenge by all three fungi (Torosantucci *et al.*, 2005, 2009; Rachini *et al.*, 2007).

The two fungal vaccines currently most advanced in the clinical pipeline are both for candidiasis. In addition to the aforementioned Sap2-based vaccine, another candidate vaccine is based on one of two *C. albicans* adhesin proteins from the same gene family (ALS), namely ALS1p and ALS3p, which are involved in recurrent vulvovaginal candidiasis, biofilm formation, and fluconazole resistance (Roudbarmohammadi *et al.*, 2016). Recombinant antigens prepared from the N-termini of both ALS1p (rALS1p-N) and ALS3p (rALS3p-N) protected immunocompetent and immune-suppressed mice from disseminated and oropharyngeal candidiasis with *C. albicans* and non-*albicans* species (Ibrahim *et al.*, 2006; Spellberg *et al.*, 2006). rALS3p-N, which induces similar CMI, but broader AMI than its ALS1 counterpart, is the moiety included in a vaccine (from NovaDigm Therapeutics, United States) that is currently in Phase 1 clinical trials with encouraging results (Spellberg *et al.*, 2008a; Baquir *et al.*, 2010; Schmidt *et al.*, 2012). Interestingly, although the rALS3p-N-based vaccine-mediated protection via T_h1/T_h17 CMI in mice, serum antibody titers predicted vaccine efficacy against *Candida* (Spellberg *et al.*, 2008a; Lin *et al.*, 2009). Notably, this vaccine also protected mice against systemic infection with various, including methicillin-resistant strains of *Staphylococcus aureus* entirely via CMI without B-cell help (Spellberg *et al.*, 2008b; Lin *et al.*, 2009). In an interesting contrast, another recombinant vaccine for *Candida* being developed by NovaDigm is completely dependent on AMI; the vaccine antigen is the N-terminal region of another GPI-anchored cell surface protein, Hyr1 that is expressed on *C. albicans* hyphae and responsible for the yeast's resistance to phagocytic killing. Antibodies elicited against Hyr1 directly neutralize this function rendering the yeast susceptible to killing by neutrophils and tissue phagocytes and the rHyr1-N vaccine as well as passively administered anti-rHyr1 antibody protect immunocompetent and immune-suppressed mice against disseminated candidiasis with *C. albicans* and non-*albicans* species (Luo *et al.*, 2011).

The concept that AMI and CMI are distinct arms of immunity that pertain to certain microbes, for example, AMI mediates protection against extracellular microbes and CMI mediates protection against intracellular microbes, has been challenged by the discovery of antibody functions that augment and modulate cellular immunity (Casadevall and Pirofski, 2011). Nonetheless, certain vaccine antigens are currently understood to work primarily through adaptive CMI, especially CD4⁺ and CD8⁺ T-cells that provide direct protection and immunological memory. For example, immunization with a peptide (P10) derived from gp43, a major antigen of the dimorphic fungus *P. brasiliensis*, reduced organ fungal burden in a murine *P. brasiliensis* respiratory infection model alone and synergistically with various antifungal drugs. In this model, protection correlated with higher levels of the pro-inflammatory T_h1 cytokines IL-12 and IFN γ , and lower levels of the anti-inflammatory T_h2 cytokines IL-4 and IL-10 (Marques *et al.*, 2006). Similar T_h1-mediated protection was afforded by *P. brasiliensis* heat shock protein (Hsp)-60 (de Bastos Ascenço Soares *et al.*, 2008). Cryptococcal mannoproteins (terminally mannosylated glycoproteins) are recognized by mannose-binding molecular pattern receptors on DCs, which in turn induce in vitro antigen-specific proliferation of CD4⁺ and CD8⁺ T-cells obtained from both HIV⁺ and HIV⁻ individuals (see Levitz *et al.*, 2015). T_h1-immunity, mediated by IFN γ , was also responsible for protection against lethal *Coccidioides posadasii* respiratory challenge in mice immunized with recombinant coccidioidal proteins, the cell wall component Ag2/PRA, and secreted protein CSA (either alone, or together as a bivalent unit) (Shubitz *et al.*, 2006), or a synthetic T-cell reactive peptide derived from *C. posadasii* cell wall that is homologous to fungal aspartyl proteases (Tarcha *et al.*, 2006). A variety of studies with *A. fumigatus* proteins have shown the importance of T_h1-immunity in aspergillosis. Immunization with the recombinant hyphal protein Asp3 protected immune-suppressed mice from pulmonary aspergillosis in a CD4⁺ T-cell dependent manner (Diaz-Arevalo *et al.*, 2011). Additionally, Asp3 (also known as Pmp20), Crf1 (a cell wall glucanase), and Gel1 (a 1,3- β -glucanoyl transferase) induced a strong T_h1 response and proliferation in both healthy individuals and patients with

invasive aspergillosis (IA), and T_H1 cells recognizing all three *A. fumigatus* proteins were cross-reactive with other *Aspergillus* species as well as with *C. albicans* and other filamentous molds, zygomycetes and sordariomycetes, with release of $IFN\gamma$ and IL-17 (Stuehler *et al.*, 2015). Crf1-induced $CD4^+$ memory T_H1 cells that are protective against *A. fumigatus* also protected mice against lethal *C. albicans* challenge (Stuehler *et al.*, 2011).

Studies with antigens and allergens from *A. fumigatus* show that fungal antigenic determinants can induce pro-inflammatory T_H17 and anti-inflammatory T_{reg} cells along with or independent of T_H1/T_H2 responses. Immunization with membrane-associated GPI-anchored proteins, such as Crf1, Gel1, and another aspartyl protease, Pep1, induced specific antibody production and activated T_H1/T_{reg} cells along with T_H17 , while inhibiting T_H2 cells, and this correlated with protection of immune-suppressed mice from an *A. fumigatus* challenge (Bozza *et al.*, 2009). The role of T_H17 cells, and the T_H17 -secreted cytokines, IL-17 and IL-22, in antifungal immunity has been controversial: $T_H17/IL-17$ -mediated inflammatory mechanisms are protective in oropharyngeal candidiasis, murine PCP, pulmonary histoplasmosis and aspergillosis; whereas, on the other hand, mucosal *C. albicans* and *A. fumigatus* infection recruits T_H17 cells that cause exuberant inflammation and tissue damage (see Wuthrich *et al.*, 2011a). It is likely that $T_H17/IL-17$ function in the course of fungal disease is modulated by several factors, such as the disease state, site of infection, inoculum, and the degree of proliferation of T_H17 cells and timing/locus of IL-17 elicitation. Vaccines might be able to focus the $T_H17/IL-17$ -mediated inflammation to mediate protection. For example, subcutaneous immunization with live (*H. capsulatum*) or live-attenuated strains (*Blastomyces dermatitidis*, *C. posadasii*) promotes differentiation of naïve T-cells into T_H17 cells that produce IL-17, IL-22, and $IFN\gamma$ and recruit PMNs and phagocytes into lungs, which protects mice from lethal pulmonary challenge with these fungi independently of T_H1 cells (Wuthrich *et al.*, 2011a). IL-17A was an obligate requirement for successful vaccine immunity in these models (Wuthrich *et al.*, 2011a). A subcutaneous canine vaccine containing the same live-attenuated *B. dermatitidis* strain as above was found to elicit $IFN\gamma$, TNF α , and granulocyte macrophage-colony stimulating factor (GM-CSF) from peripheral lymphocytes in response to stimulation with *Blastomyces* cell wall antigens, and this response was found to be independent of any pre-immunization exposure to *B. dermatitidis* (Wuthrich *et al.*, 2011). Similarly, Pep1-vaccine-induced protection against pulmonary *A. fumigatus* was mediated by $IFN\gamma$, IL-17A, and IL-10, in addition to $CD4^+$ and $CD8^+$ T-cells (albeit via different activation mechanisms). However, Pep1 was still protective in the absence of IL-17A in the setting of chronic granulomatous disease (De Luca *et al.*, 2012). Similar protection was also observed with Crf1 and Gel1. These studies highlight the idea that an understanding of the cellular and molecular correlates of the immune (and inflammatory) response to fungi makes rational vaccine design eminently possible.

In the setting of compromised immunity (especially neutropenia) natural and antigen-induced $Foxp3^+$ T_{reg} cells produce high levels of IL-10 and TGF β and induce a protective tolerance to *A. fumigatus* that is protective and counters the chronic immunopathology observed in experimental models, patients with IA and allergic bronchopulmonary aspergillosis (ABPA) (see Bedke *et al.*, 2014), and *Pneumocystis carinii* in experimental *Pneumocystis* pneumonia (PCP) (Hori *et al.*, 2002). Notably, T_{reg} -mediated immunosuppression via IL-10 and TGF β has been implicated in fungal persistence, but may contribute to immunological memory (see Romani and Puccetti, 2006). Tr1 cells are presumed to protect from T_H1/T_H17 -mediated inflammatory processes, including autoimmunity (Bedke *et al.*, 2014). Along these lines, immunization with a peptide (p41), an immunodominant epitope within Crf1, and zymosan used as an adjuvant, induced Tr1, or $CD4^+$ $Foxp3^-$ T_{reg} cells, that produce high IL-10 relative to $IFN\gamma$ but no IL-4. In murine IA models, Crf1/p41-induced Tr1 cells reduced inflammatory infiltrates and neutrophils in the lungs with no concomitant effect on lung fungal burden and suppressed overall expression of T_H1/T_H17 -related transcription factors in thoracic lymph node T-cells. However, CpG ODNs, when used as adjuvants in parallel experiments showed the opposite effects, namely, induction of $Foxp3^+$ T_{reg} cells, an increase in $IFN\gamma$ levels, and expression of T_H1/T_H17 -related transcripts (Bedke *et al.*, 2014). These observations indicate that the choice of adjuvant and vaccine antigen influence the balance between fungal elimination, inflammation, and damage control in the setting of high or low degrees of inflammation.

Specific challenges to fungal vaccine development

Fungal organisms can cause a broad spectrum of diseases ranging from self-limited cutaneous lesions to acute and chronic pulmonary disease to disseminated and deadly systemic disease, but most fungi do not cause disease in individuals with intact immunity. Therefore, it was not until the medical advances, introduction of cytotoxic therapies and regular use of intravascular catheters, and broad-spectrum antibiotic development that began in the 1950s and were followed by the HIV/AIDS pandemic in the late 1970s, that fungal diseases assumed medical relevance. However, even with the subsequent unprecedented expansion of populations of people with various degrees of immune suppression that render them vulnerable to fungal diseases with high morbidity and mortality, invasive mycoses do not garner the degree of attention by clinicians, scientists and policymakers as do bacterial and viral diseases. This under-appreciation is a likely reason why the development of vaccines for fungal diseases has lagged behind those for other microbes (Spellberg, 2011) and why to date only two vaccines for one fungal disease have advanced to clinical trials. This is worrisome, especially because fungal infection is very common and the risk of disease is high if the host immunity falters. For instance, the Mississippi and Ohio River valley in the United States is endemic for the dimorphic fungus, *H. capsulatum* (Nett *et al.*, 2015) with high mycelial concentration in the regional soil. Another area of environmental risk is the Pacific Northwest of Canada and the United States, where a low level outbreak of cryptococcosis due to *C. gattii* has been emergent since 1999 (Datta *et al.*, 2009a,b). Therefore, fungal vaccines are a still unmet, but crucial clinical need that is likely to increase with the confluence of possible shifts/increases in fungal habitats related to global warming, growth of solid organ transplantation, and continued development of therapies for malignancy and inflammatory diseases that impair host immunity.

Since vaccine-mediated immunity (AMI and CMI) depends upon the host's immunological status, a common concern for all vaccines is their efficacy in the setting of impaired immunity. Although this concern has been allayed for certain antifungal vaccines (Spellberg, 2011; Nanjappa *et al.*, 2012), and rational vaccine design can lead to the configuration of vaccines and developments of adjuvants that skew the response in the most advantageous way for a given patient. In this regard, the emerging field of precision medicine provides hope that vaccine/adjuvant combinations that will optimize the type of immune response that will benefit (an individual) patient can be identified. Other challenges to vaccine design, such as poor immunogenicity or immunosuppressive properties of certain fungal antigens, such as GXM (O'Meara and Alspaugh, 2012) can likely be overcome by the use of adjuvants that counteract the undesired properties of an antigen, and/or discovery of novel antigens with more beneficial effects. Another important challenge to fungal vaccine development is that many fungal diseases arise from reactivation of a latent focus. In this regard, fungal vaccines that are designed for high risk patients could need to exert a direct therapeutic effect and/or be targeted to processes that mediate dissemination. Finally, there are important regulatory and fiscal barriers to fungal vaccine development (see Spellberg, 2011; Hamad, 2012; Moriyama *et al.*, 2014).

Passive Immunotherapeutic Modalities

Passive immunotherapy is a modality, whereby preformed products of the immune response are exogenously administered to the host. This is in contrast to the aforementioned active immunotherapeutic modalities (such as vaccines) where the administered product is given to induce a host immune response. Passive immunotherapy is usually focused on the microbe and can be effective largely independently of the host immune status. Therefore, this modality can be rapidly deployed to provide immediate immunity, and is generally suitable for use in immunocompromised patients. Passive immunotherapy leverages a number of pathogen-specific cellular or humoral effector mechanisms, including poly- or monoclonal antibodies (mAbs) with fungistatic or fungicidal functions, administration of chemical messengers (cytokines/chemokines) associated with innate and adaptive responses, adoptive transfer of antigen/pathogen-primed immune cells from a donor to a recipient, and antimicrobial peptides (AMPs) directly acting on the microbe.

Passive antibody therapy for fungal diseases

Passive administration of preformed antibody is a powerful anti-infective strategy with roots in late 19th century that was validated as the first form of antimicrobial therapy in the first quarter of the 20th century. Antibodies, with their signature ability to recognize a specific cognate antigen, mediate antimicrobial activity through a variety of mechanisms, including: promotion of phagocytosis via opsonization, activation of complement, neutralization of viruses and toxins, sequestration of soluble antigens, modulation of inflammatory processes, direct ADCC, and impact on microbial metabolism (reviewed in Casadevall and Pirofski, 2011). With the advent of antibiotics in early 1940s, steep logistical and biological challenges impacted the feasibility of passive antibody therapy ("serum therapy"), which led to the virtual abandonment of this modality, except for niche conditions such as treatment of toxins produced by tetanus, *Clostridium botulinum*, snake/scorpion venom, and certain viral diseases. However, introduction of hybridoma technology and mAbs in the 1970s, as well as currently available tools based on them, have led to the ability to overcome the difficulties of serum therapy. Although, to date, interest in passive antibody therapy for infectious diseases has not risen to pre-antibiotic era levels, mAbs are widely used in oncology and rheumatology, and a number of agents are in advanced trials for infectious diseases.

Immunotherapy with mAbs

Protective mAbs against fungal antigens

Fungal disease pathogenesis elicits antibody responses to fungal surface and intracellular antigens, such as polysaccharides, proteins, pigments, and glycoproteins/glycolipids (Casadevall and Pirofski, 2007b), but the protective role of such antibodies has been debated. Experimental and clinical observations prior to the 1990s suffered from certain methodological limitations that likely led to inconsistent results concerning the ability of antibodies to protect against disease with *C. neoformans* and *C. albicans*, the yeasts most extensively studied (see Casadevall, 1995). However, subsequent experimental studies, many of which were performed with mAbs produced via hybridoma technology, provided strong evidence for that AMI can mediate protection against fungi. Such studies corroborated the clinical observation that certain invasive fungal infections occur in patients with primary antibody deficiencies, such as common variable immunodeficiency/CVID, X-linked agammaglobulinemia/XLA, and Good syndrome (Macura *et al.*, 2003; Lucas *et al.*, 2010; Marr *et al.*, 2012; Malphettes *et al.*, 2015). Although, historically, direct associations between antibody deficiency and invasive fungal disease were largely lacking, more recent studies have linked antibody repertoire defects to the pathogenesis of certain fungal diseases (Hori *et al.*, 2002; Rohatgi and Pirofski, 2015). In this regard, the generation of mAbs made it possible to interrogate the response to a fungus and identify specific antibodies with the ability to alter the host response to fungi to benefit the host. Generation and description of protective mAbs against *C. neoformans* (Dromer *et al.*, 1987) and murine *P. carinii* (Gigliotti and Hughes, 1988) in the late 1980s, and subsequently against a number of medically important fungi (including *A. fumigatus*, *C. albicans*, *H. capsulatum*, and *P. brasiliensis*) (see Casadevall and Pirofski, 2012) provided strong evidence to support the feasibility of using mAbs as agents of immunotherapy.

A discussion of antifungal mAbs is incomplete without consideration of antibody functional efficacy and structure–function relationships. mAb-based studies revealed that the same B-cell may produce antibodies to the same antigen, but with disparate

Table 1 Protective antibodies to fungal determinants

<i>Fungus</i>	<i>Determinant</i>	<i>Agent</i>	<i>Effect</i>	<i>Notes</i>	<i>Reference</i>
<i>Aspergillus</i> species	β -1,3 Glucan (cell wall)	Vaccine antigen with diphtheria toxoid	Protected mice against lethal challenge with <i>Aspergillus fumigatus</i> conidia	In vivo; also, immune serum inhibited conidial growth in vitro	Torosantucci <i>et al.</i> (2005)
	Pep1p protease; GPI-anchored Gel1p and Crf1p; α - and β -1,3-glucans (cell wall)	Vaccine antigen	Increased survival, reduced fungal burden in lung and brain; reduced inflammatory cell recruitment in lung	In vivo; vaccine antigens delivered with CpG or via DC pulsing conferred T_H1 -dependent protection, with T_{reg} and/or T_H17 activation	Bozza <i>et al.</i> (2009) and Stuehler <i>et al.</i> (2011)
	Asp f3 allergen (peroxisome)	Vaccine antigen	Elicits protective IgG2a response against invasive aspergillosis; induces CMI which clears fungal elements from lungs	In vivo; corticosteroid-immunosuppressed mouse model of pulmonary aspergillosis	Ito <i>et al.</i> (2006)
	Asp f16 allergen	Vaccine antigen with CpG ODN adjuvant	Increased survival; reduced lung fungal burden; better lung pathology index; strong DTH response	In vivo; murine pulmonary aspergillosis model; protection mediated by T_H1 responses with increased IFN- γ and reduced IL-4 and IL-10; vaccine induces DC maturation and activation, and stimulates innate CMI	Bozza <i>et al.</i> (2002)
	Heat-killed <i>Saccharomyces cerevisiae</i>	Vaccine antigen with alum adjuvant	Antigen promotes T-cell proliferation and production of IFN- γ , IL-6 and IL-17A, and induces antibodies to fungal glucan and mannan	Heterologous protection against various yeast and molds	Un-published data summary in Stevens <i>et al.</i> (2011)
	100 KDa cell wall glycoproteins	mAb (IgG1, "A9")	High affinity binding to <i>A. fumigatus</i> hyphal cell wall peptides; hyphal growth inhibition	In vitro; also, protected mice against lethal systemic challenge and reduced fungal burden in vivo	Chaturvedi <i>et al.</i> (2005)
<i>Blastomyces dermatidis</i>	Attenuated (BAD-1 adhesin knockout) mutant strain; cell wall/membrane antigen derived from vaccine strain	Vaccine antigen	Prolonged survival in murine pulmonary and systemic infection models, lowered fungal burden (even with non-isogenic strains), and enhanced DTH and type 1 cytokine responses	In vivo; protection mediated by strong vaccine-induced $CD4^+$ T-cell responses, with IFN- γ ; protection adoptively transferable via lymphoid cells; requires presence of adapter protein Card9, which leads to T_H17 cell development	Wuthrich <i>et al.</i> (2000) and Wang <i>et al.</i> (2014)
			Safe, tolerable, and immunogenic in dogs	In vivo; elicits T-cell response marked by IFN- γ and GM-CSF	Wuthrich <i>et al.</i> (2011)
<i>Candida albicans</i>	β -1,3 Glucan (cell wall)	Vaccine antigen with diphtheria toxoid or MF59 adjuvant	Protected mice against both systemic and mucosal (vaginal) candidiasis	In vivo; protection also via passively transferred immune serum, immune vaginal fluid, polyclonal antibody to β -glucan	Torosantucci <i>et al.</i> (2009) and Pietrella <i>et al.</i> (2010)
	<i>Candida</i> mannans (cell wall)	Vaccine antigen complexed with liposomes	Prolonged survival, reduced organ fungal burden in systemic model, and accelerates clearance of fungus from vaginal tissue	In vivo; murine systemic infection model, using both normal and SCID mice, and intravaginal infection model; protection mediated by AMI	Han and Cutler (1995) and Han <i>et al.</i> (1998)
	Secretory aspartyl proteinase (Sap2) native or recombinant (rSap2t)	Vaccine antigen in "CT" adjuvant	Protected against experimental vaginal candidiasis, accelerated fungal clearance from the vagina Improved survival in mice	In vivo; rat intravaginal model; vaccination elicited Sap2-specific antibodies; protection also depends on T-cell response	De Bernardis <i>et al.</i> (1997) and Sandini <i>et al.</i> (2011) Spellberg <i>et al.</i> (2008a)

Table 1 Continued

<i>Fungus</i>	<i>Determinant</i>	<i>Agent</i>	<i>Effect</i>	<i>Notes</i>	<i>Reference</i>
	Agglutinin like sequence adhesins (Als1p/Als3p/rAls3p-N)	Vaccine antigens in alum adjuvant		In vivo; murine systemic model; adjuvant necessary	
			high IgG and IgA titers	for protection; protection mediated by strong vaccine-induced T-cell responses	Moriyama <i>et al.</i> (2014)
	Recombinant Hyr1p (cell wall)	Vaccine antigen	Improved survival in mice, reduced lung fungal burden. Also, active against non- <i>albicans</i> <i>Candida</i> species	Phase 1 dose escalation study volunteers In vivo; murine systemic immune competent or –compromised model; protection mediated by neutralization of virulence function of Hyr1p (which hinders phagocytosis) and enhancement of PMN function	Luo <i>et al.</i> (2011)
	Fructose bisphosphate aldolase (cell wall)	Vaccine antigen	Prolonged survival, reduced organ fungal burden	In vivo; murine systemic infection model; DC-based immunization; peptide not restricted by MHC-II; protection via AMI; recognized by human salivary IgA	Xin and Cutler (2011) and Calcedo <i>et al.</i> (2012)
	Live-attenuated <i>C. albicans</i> tet-NRG1 strain	Vaccine antigen	Improved survival in healthy and B-cell deficient, but not T-cell deficient, mice	In vivo; murine systemic infection model	Saville <i>et al.</i> (2009)
	<i>C. albicans</i> whole sonicate (cell lysate)	Vaccine antigen to prepare IgY antibody in chicken egg yolk	Reduced fungal adherence to human pharynx carcinoma cell line FaDu	In vitro; also, in vivo, decreased fungal burden, and limited dissemination of oral candidiasis in mice	Ibrahim el <i>et al.</i> (2008)
	Sap2 native or recombinant (rSap2t)	mAb (IgG1, “GF1”; IgM)	Passive transfer of anti-rSap2t mAbs reduced vaginal fungal burden	In vivo; rat intravaginal model	De Bernardis <i>et al.</i> (1997) and Sandini <i>et al.</i> (2011)
		Genetically engineered V _H and V _L domain antibodies	Inhibited <i>C. albicans</i> adherence to rat vaginal epithelial cells and accelerated fungal clearance	In vitro and in vivo; effect seen with both fluconazole-susceptible and fluconazole-resistant <i>C. albicans</i>	De Bernardis <i>et al.</i> (2007)
	β -1,3 Glucan (cell wall)	mAb (IgG2b, “2G8”)	mAb Binding showed direct antifungal, growth-inhibiting action against <i>C. albicans</i> ; protected mice against vaginal candidiasis	In vitro and in vivo	Torosantucci <i>et al.</i> (2009) and Pietrella <i>et al.</i> (2010)
	Cell wall mannoproteins	mAb (IgM, “C7”); mAb against MP58	Protected mice against invasive candidiasis	In vivo; C7 binds <i>C. albicans</i> cell wall mannoprotein, and als3	De Bernardis <i>et al.</i> (1997), Sevilla <i>et al.</i> (2006), Viudes <i>et al.</i> (2004), and Brena <i>et al.</i> (2007)
	β -1,2-Linked mannotriose (cell wall)	mAb (IgM; B6.1)	Prolonged survival, reduced organ fungal burden in systemic model, and accelerates clearance of fungus from vaginal tissue	In vivo; murine systemic infection model, using both normal and SCID mice, and intravaginal infection model	Han and Cutler (1995) and Han <i>et al.</i> (1998)
	HSP90 (cell surface)	mAbs	Prolonged survival after challenge with fluconazole-sensitive or –resistant <i>C. albicans</i> , improved renal clearance	In vivo; murine acute and chronic models of invasive candidiasis; protection associated with neutralization of protein	Matthews <i>et al.</i> (1995)

(Continued)

Table 1 Continued

Fungus	Determinant	Agent	Effect	Notes	Reference
<i>Candida dubliniensis</i>		Human recombinant mAb ("mycograb")	Active against a wide range of <i>Candida</i> species; synergy with Amphotericin B; reduced organ fungal burden in murine candidiasis	binding properties of HSP90 Preclinical assessment	Matthews <i>et al.</i> (2003)
	Fructose Bisphosphate aldolase	mAb (IgM, "E2-9")	Prolonged survival, reduced organ fungal burden	In vivo; murine systemic infection model	Xin and Cutler (2011)
	Mannan	Vaccine antigen conjugated to human serum albumin	Engaged both AMI and CMI; Increased anti-mannan IgM, IgG and IgA levels, induced CD4 ⁺ T-cells and T _H 1 cytokines, activated CD25 ⁺ B-cells	In vivo, in immunized rabbit	Paulovicova <i>et al.</i> (2007)
<i>Cryptococcus neoformans</i>	GXM (cell surface)	Vaccine antigen conjugated to tetanus- or diphtheria-toxoid	Promoted survival, reduced organ cryptococcal burden	In vivo; murine systemic infection model; protection mediated via AMI	Devi (1996), also see Zaragoza <i>et al.</i> (2009)
	P13 Peptide mimotope of GXM	Vaccine antigen conjugated to tetanus- or diphtheria-toxoid	Prolonged survival, reduced serum GXM levels	In vivo; murine acute and chronic systemic infection model; protection mediated via AMI, T _H 1 cell responses, and vaccine-induced immunomodulation	Datta <i>et al.</i> (2008)
	CneF (culture filtrate antigen complex); cell surface mannoprotein purified from CneF	Vaccine antigens	Promoted survival, decreased organ fungal burden, reduced organ inflammatory damage	In vivo; murine systemic infection model; T-cell dependent protection mediated via TNF- α , IFN- γ , and IL-2; mannosylation of peptide antigen is critical for optimal T-cell responses	Specht <i>et al.</i> (2007) and Mansour <i>et al.</i> (2004)
	β -1,3 Glucan (cell wall)	mAb (IgG2b, "2G8")	Reduced brain and liver fungal burden in both immune competent and neutropenic mice	In vivo; murine systemic cryptococcal infection model; also, in vitro, binds to cryptococcal cell wall, inhibits growth, reduces capsular thickness	Rachini <i>et al.</i> (2007)
	GXM	mAb	Prolonged survival and decreased fungal burden in <i>C. neoformans</i> -infected mice	In vitro and in vivo; well-documented beneficial effects in murine systemic and pulmonary infection models	Maitta <i>et al.</i> (2004a), Dromer <i>et al.</i> (1987), Sanford <i>et al.</i> (1990), Mukherjee <i>et al.</i> (1992), Fleuridor <i>et al.</i> (1998), and Beenhouwer <i>et al.</i> (2007)
	Glucosyl-ceramide (cell wall glycolipid)	Polyclonal Ab (IgG1) purified from patient sera	Inhibited cell budding and cell growth in a complement-independent manner	In vitro; effect demonstrable in both acapsular and encapsulated cryptococcal strains	Rodrigues <i>et al.</i> (2000)
	Melanin (cytoplasm)	mAb ("11B11," "6D2")	Promoted survival, reduced organ cryptococcal burden	In vivo; murine systemic infection model; also, in vitro, mAb reduces the growth rate of melanized <i>C. neoformans</i> cells	Rosas <i>et al.</i> (2001)
	Cell wall/cytoplasm associated proteins	Vaccine antigen	Promoted survival, reduced lung cryptococcal burden,	In vivo; murine pulmonary infection model; protection via increased pro-	Chaturvedi <i>et al.</i> (2014)

Table 1 Continued

<i>Fungus</i>	<i>Determinant</i>	<i>Agent</i>	<i>Effect</i>	<i>Notes</i>	<i>Reference</i>
<i>Coccidioides posadasii</i>	Pmp1 (peroxisome), recombinant	Vaccine antigen with lipid-based adjuvant	increased <i>C. gattii</i> -specific antibody production Reduced organ fungal burden, prolonged survival	inflammatory T _H 1 cytokine recall responses In vivo; murine systemic and pulmonary infection models; also, antigen reacted with sera of patients of coccidioidomycosis	Orsborn <i>et al.</i> (2006)
	Pep1 aspartyl protease (cell wall and secreted)	Vaccine antigen with CpG ODN adjuvant	Promoted survival and reduced fungal burden	In vivo; T-cell reactive antigen; murine pulmonary coccidioidomycosis model	Tarcha <i>et al.</i> (2006)
	Ag2/Pra + recombinant PrP2 (both Proline-rich cell wall proteins with distinct T-cell epitopes)	Vaccine antigens in adjuvant	Improved survival, reduced lung fungal burden	In vivo; murine pulmonary infection model; combination of antigens provided better protection than single antigens	Herr <i>et al.</i> (2007)
	Heat-killed or live <i>S. cerevisiae</i>	Vaccine antigen delivered subcutaneously (HKSc) or orally (Live Sc)	Promoted survival and reduced organ fungal burden in murine <i>C. posadasii</i> systemic infection model	In vivo; antigen promotes T-cell proliferation and production of IFN γ , IL-6 and IL-17A, and induces antibodies to fungal glucan and mannan, which may account for heterologous protection	Liu <i>et al.</i> (2011) and Capilla <i>et al.</i> (2009)
<i>Coccidioides immitis</i>	Attenuated live mutant strain	Vaccine antigen in EP67 adjuvant	Increased survival, reduced inflammatory pathology, lowered fungal burden in lung	In vivo; murine pulmonary infection model; protection mediated by initial PMN migration; EP67 adjuvant (C5a analog) helps down-regulate later PMN presence in lungs and promotes protection; requires T _H 17	Hung <i>et al.</i> (2012) and Wuthrich <i>et al.</i> (2011)
<i>Fonsecaea pedrosoi</i>	Polypeptides containing MHC-binding T cell epitopes	Vaccine antigen in CpG or Glucan particle adjuvant	Reduced in fungal burden; antigen in glucan particle was more efficient in promoting survival	In vivo; murine pulmonary infection model; protection mediated by CD4 ⁺ and CD8 ⁺ T-cells	Hurtgen <i>et al.</i> (2012)
	Melanin (cytoplasm)	Vaccine antigen eliciting AMI	Purified antibodies against melanin inhibited fungal growth, increased phagocytosis and destruction of conidia	In vitro	Alviano <i>et al.</i> (2004)
	Glucosyl-ceramide (cell wall)	mAbs	Reduced fungal growth, enhanced phagocytosis of conidia by murine macrophages	In vitro; protection mediated via mAbs specific to <i>F. pedrosoi</i> glucosyl-ceramide antigens	Nimrichter <i>et al.</i> (2004)
<i>Histoplasma capsulatum</i>	Live yeast	Vaccine antigen	Reduced lung fungal burden and prolonged survival in immunocompromised mice	In vivo; CD4-depleted mouse pulmonary infection model; protection dependent upon MHC-I-restricted memory CD8 ⁺ T-cells secreting TNF- α , IFN- γ , and GM-CSF (in absence of CD4)	Wuthrich <i>et al.</i> (2003)
	Sec31 protein, recombinant	Vaccine antigen Vaccine antigen	Promoted survival in both sublethal and lethal infections, and reduced lung and spleen fungal burdens	In vivo; murine pulmonary infection model; protection dependent upon presence of V β 4 ⁺ T-cells in the lungs	Scheckelhoff and Deepe (2006)

Table 1 Continued

<i>Fungus</i>	<i>Determinant</i>	<i>Agent</i>	<i>Effect</i>	<i>Notes</i>	<i>Reference</i>
<i>Paracoccidioides brasiliensis</i>	HSP60 (cell surface), recombinant		Prolonged survival, limited fungal replication	In vivo; induces protective immune responses dependent on $V\beta$ 8.1/8.2 ⁺ CD4 ⁺ T-cells; requires T _H 17; in absence of CD4 ⁺ T-cells, DCs stimulate CD8 ⁺ T-cells for protection	Wuthrich <i>et al.</i> (2011), Gomez <i>et al.</i> (1995), and Lin <i>et al.</i> (2005)
		mAb (IgG1, IgG2a)	Prolonged survival, reduced fungal burden in <i>H. capsulatum</i> -infected mice	In vivo; increased IL-12 and TNF- α , decreased IL-4 and IL-10. Also, in vitro, reduced intracellular fungal survival and increased phagolysosomal fusion of macrophages	Guimaraes <i>et al.</i> (2009)
	Histone H2B-like protein (cell surface)	mAb	Protected mice against lethal pulmonary histoplasmosis	In vivo; protection mediated via enhancements in IL-4, IL-6, and IFN- γ in the lungs. Also, mAb alters intracellular fate of <i>H. capsulatum</i>	Nosanchuk <i>et al.</i> (2003)
	Recombinant yeast protein PB27 (cell surface and cytosolic)	Vaccine antigen	Prolonged survival in mouse systemic infection model, reduced organ fungal burden and lung granuloma	In vivo; protection mediated by high IgG2b and IgG1, as well as IFN- γ and TGF- β ; enhancement of fluconazole efficacy	Fernandes <i>et al.</i> (2011)
	HSP60	Vaccine antigen	Reduced fungal burden and lung damage, protected mice against moderate and lethal pulmonary challenge	In vivo; T _H 1-dependent protection, centered around IFN- γ	de Bastos Ascenço Soares <i>et al.</i> (2008)
	Heat-killed <i>S. cerevisiae</i> expressing recombinant gp43	Vaccine antigen	Reduced fungal growth and lung damage; enhanced IFN γ and IL-12 in lung and spleen	In vivo; T _H 1-dependent protection; murine systemic infection model	Assis-Marques <i>et al.</i> (2015)
	P10 (peptide derived from gp43)	Vaccine antigen, as fusion peptide with FLiC or in complete/incomplete Freund's adjuvant	Reduced fungal growth and lung damage; strong specific immune response even in immune compromised hosts; action synergistic with antimicrobial agents	T _H 1-dependent protection (P10 has a CD4 ⁺ T-cell epitope); murine pulmonary infection model (healthy or immune-suppressed via steroid)	Braga <i>et al.</i> (2009) and Munoz <i>et al.</i> (2014)
	<i>Mycobacterium leprae</i> HSP65	DNA vaccine	Reduced organ fungal burden and organ damage in murine systemic infection; functions as an immunomodulator	In vivo; protection mediated via priming strong T _H 1 response and downregulating T _H 2 cytokines	Ribeiro <i>et al.</i> (2010)
	gp43 (Secreted)	mAb 3E	Reduced fungal burden and lung inflammation; enhanced IFN γ levels in lungs	In vivo; murine pulmonary and systemic infection models; also, in vitro 3E enhanced phagocytosis of yeast cells	Buissa-Filho <i>et al.</i> (2008)
	gp70 (intracellular/secreted)	mAb specific for gp70	Diminished lung granulomas in mice with <i>P. brasiliensis</i> infection	In vivo; mAb counteracts adverse, disease-enhancing effects of gp70	de Mattos Grosso <i>et al.</i> (2003)
<i>Pneumocystis carinii</i> (murine); <i>Pneumocystis jirovecii</i> (human)	Major cell surface glycoprotein (MSG)	Vaccine antigen	Promoted survival, and reduced lung fungal burden and injury in infected rats	In vivo; immunocompromised rat model of <i>Pneumocystis</i> pneumonia; vaccine elicited AMI	Theus <i>et al.</i> (1998)
	p55			In vivo; protection mediated by both CMI and AMI in	Feng <i>et al.</i> (2011)

Table 1 Continued

Fungus	Determinant	Agent	Effect	Notes	Reference
		DNA vaccine targeting protein p55	Reduced organism burdens; improved histological scores	immunosuppressed rat model	
	Cell surface Glycoprotein A (gpA)	mAb 2B5	In murine <i>P. carinii</i> pneumonia model, mAb selectively destroyed gpA variant-bearing <i>P. carinii</i> subpopulation by attacking trophozoites	In vivo; mAb specific for one variant of gpA of murine <i>P. carinii</i>	Gigliotti <i>et al.</i> (1996)
	Kex 1 (kexin-like protease); kex 1 homolog, recombinant antigen A12	mAb (IgM, "4F11"; IgG switch variant, "4F11G1")	Protected SCID mice against <i>Pneumocystis</i> pneumonia, reduced fungal burden	In vivo; mAbs bind to intracellular, membrane-bound antigens; 4F11G1 also recognized multiple epitopes on human <i>P. jirovecii</i> isolates	Gigliotti <i>et al.</i> (2002) and Wells <i>et al.</i> (2004, 2006)

Abbreviations: AMI, antibody-mediated immunity; CMI, Cell-mediated immunity; CSF, colony stimulating factor; DC, Dendritic cells; DTH, delayed type hypersensitivity; GM, granulocyte macrophage; GXM, Glucuronoxylomannan; HSP, heat shock protein; IFN, interferon; IL, interleukin; mAbs, monoclonal antibodies; MHCs, major histocompatibility complexes; ODN, oligodeoxynucleotides; PMNs, polymorphonuclear neutrophils; SCID, severe combined immunodeficiency.

epitope specificity and drastically different protective efficacy (Mukherjee *et al.*, 1995). Again, GXM-reactive murine mAbs of isotypes IgG1 and IgG3 derived from the same B-cell were, respectively, protective and non-protective/disease-enhancing following cryptococcal challenge in mouse models (Yuan *et al.*, 1995, 1997). Similar observations were made with human IgM mAbs prepared against GXM in transgenic mice, with different binding specificity, germline heavy-chain variable region gene usage, and protective efficacy (Maitta *et al.*, 2004a). Additionally, there is evidence that for fungal infections, the extent of antibody-mediated protection may vary depending on the isotype/subtype and titer of the fungus-specific antibody (Taborda *et al.*, 2003) and the genetic (major histocompatibility complex/MHC) background of the host (Rivera and Casadevall, 2005) among other factors. In aggregate, this body of evidence supports the concept that the presence of non-protective fungus-specific antibodies in polyclonal immune serum may reduce the degree of protection afforded by the protective antibodies therein. This might have been a driver of the initial inconsistencies observed in serum therapy. Indeed, monoclonal forms of such non-protective antibodies have now been described for *C. albicans*, *H. capsulatum*, and *C. neoformans* (Casadevall and Pirofski, 2007b). Any design and utilization of mAbs as immunotherapeutic agents for specific fungal infections must, therefore, consider that fungi can elicit antibodies that do and do not benefit the host in the setting of fungal infection. On the other hand, in the vast majority of normal individuals who rarely develop disease with most fungi, the aforementioned polyclonal antibody response might balance pro- and anti-inflammatory responses with the result being damage control. Therefore, a response that might limit damage in normal individuals might be insufficient in those with impaired immunity who are likely to have/develop a higher fungal burden and/or a breakdown in latency that leads to dissemination.

Studies to develop protective mAbs against fungi have often progressed in tandem with the search for vaccine antigens, including fungal cell wall components (e.g., glucan/mannan polysaccharides, glycoproteins, glycolipids), non-cell wall surface molecules (e.g., cryptococcal GXM, *Histoplasma* Hsp60), cytoplasmic/nuclear proteins (including histone-like proteins and those involved in signaling pathways) and other processes. For instance, the aforementioned vaccine studies on β -glucan yielded the cross-reactive mAb 2G8, which was protective against *C. neoformans*, *C. albicans*, and *A. fumigatus* (Torosantucci *et al.*, 2005, 2009; Rachini *et al.*, 2007). Further examples of protective mAbs against fungal antigens of interest to immunotherapy are summarized in Table 1.

Of note are two mAb-based therapeutic agents that advanced to clinical development. Efungumab (Mycograb) is a recombinant single-chain (scFv) anti-HSP90 antibody of human origin, which protected mice from *Candida tropicalis* (Matthews *et al.*, 2003; Nooney *et al.*, 2005; Hodgetts *et al.*, 2008) and potentiated the action of antifungals of various classes upon coadministration. Combined with Amphotericin B, caspofungin (an echinocandin), or fluconazole, Mycograb was more effective against eight clinical isolates of *C. neoformans* than the individual drug treatments alone, especially in the case of Amphotericin B, which additionally resolved *C. albicans*, *Candida krusei*, and *Candida glabrata* infections (Nooney *et al.*, 2005). Mycograb with caspofungin increased the caspofungin-susceptibility of *Candida* species (Matthews *et al.*, 2003; Nooney *et al.*, 2005; Hodgetts *et al.*, 2008), and was effective and well tolerated in fungal sepsis when combined with liposomal Amphotericin B or caspofungin (Sutherland and Ellis, 2008). In a clinical trial with patients with candidemia, Mycograb reduced *Candida*-attributable mortality and showed improved clearance of fungal cultures (Pachl *et al.*, 2006). Unfortunately, production difficulties and other issues forced the abandonment of this potentially promising therapy. The other agent is mAb 18B7, a mouse-derived IgG1 against *C. neoformans*, which was studied in a clinical trial and found to be safe and to reduce serum GXM when used at high doses (Larsen *et al.*, 2005). However, further clinical development of this promising mAb has been hampered by funding issues. These examples illustrate how nonscientific factors can negatively influence the development of therapeutic options.

Radioimmunotherapy

Developed initially for cancer treatment, radioimmunotherapy (RIT) for infectious diseases is an immunotherapeutic modality in which antibodies labeled with radionuclides deliver lethal irradiation to a target cell. The GXM-reactive IgG1 mAb 18B7 (mentioned above) and *Histoplasma* cell wall protein-reactive IgM mAb 9C7 labeled with β -emitter rhenium-188 or α -emitter bismuth-213 were protective against, respectively, experimental *C. neoformans* and *H. capsulatum* infections in a radiation dose-dependent manner (Dadachova and Casadevall, 2006, 2009). In experimental models of high-burden cryptococcal infections, the therapeutic effect of RIT was mediated via fungus-targeting mechanisms (e.g., direct killing or induction of fungal apoptosis), and reduction of fungal metabolic activity (Dadachova et al., 2006; Bryan et al., 2009) as well as host-focused alterations of the cytokine milieu (IL-2, IL-4, IL-10, TNF α , and IFN γ) (Dadachova et al., 2006). Interestingly, in vitro exposure of macrophage-like J774.16 cells or epithelial-like CHO cells to radiolabeled (via antibody binding) *C. neoformans* resulted in minimal bystander loss of membrane integrity, viability and metabolic activity (Bryan et al., 2013), thereby indicating the relative safety of this method. Successful application of *Aspergillus*-specific mAbs (JF5) for RIT of invasive pulmonary aspergillosis was recently reported (Thornton, 2014).

Immunomodulation via mAb

Although mAb-based mechanisms discussed so far are fungus-targeting via antibodies that neutralize and/or kill fungi (reviewed in Casadevall and Pirofski, 2012) certain antibodies, whether host-derived or exogenous, are able to variably modulate the host immune response to benefit the host. For example, mAb3B4, specific for a *C. albicans* germ tube surface antigen, modulated phagocytosis and bound keratin, enhancing B1 B cell compartment repopulation (Li et al., 2007). Anti-CD40 mAbs, explored for their protective potential against systemic *C. neoformans* infection, correlated with an increase in IFN γ and TNF α production and upregulation of MHC-II expression on brain microglia (Zhou et al., 2006). In a mouse model of fungal sepsis, mAb-mediated inhibition of negative costimulatory molecules, such as programmed cell death 1 (PD-1), its ligand (PD-L1), or T-lymphocyte antigen-4 (CTLA-4), enhanced survival of mice (Chang et al., 2013b) mAbs capable of inducing anti-inflammatory mechanisms have shown promise in inflammatory disorders. In a murine PCP model, an anti-CD3 mAb reduced T-cell induced inflammatory damage to lung tissue and improved outcome via depletion of CD4⁺ and CD8⁺ T-cells (Bhagwat et al., 2010), and the anti-IgE mAb (Omalizumab) successfully treated a cystic fibrosis patient with antibiotic- or prednisone-refractory ABPA (Kanu and Patel, 2008).

A most interesting example of mAb-mediated immunomodulation is afforded by *P. brasiliensis* (paracoccidioidomycosis) in which asymptomatic infection or mild disease is associated with T_H1-immunity, whereas severe disease involves suppression of delayed type hypersensitivity (DTH) responses and T_H2-immunity. In murine models of paracoccidioidomycosis, A/J are genetically resistant, able to induce mixed T_H1/T_H2 responses with IFN γ from protective CD8⁺ T-cells, whereas B10.A mice are susceptible, due to CD4⁺CD25⁺Foxp3⁺ T_{reg}-mediated induction of inhibitory CD4⁺ T-cell anergy via IL-10, TGF β , and indoleamine 2,3-dioxygenase/IDO. However, even in resistant A/J mice, T_{reg} cells inhibited localization of inflammatory T-cells to the site of infection (Felonato et al., 2012). Therefore, an anti-CD25 IgG mAb, which depleted T_{reg} cells and impaired IDO expression, negated the T_{reg}-immunosuppressive functions, reduced organ fungal burden, and increased survival of infected B10.A mice (Felonato et al., 2012). This example underscores the importance of molecular mechanism-based design of immunotherapeutic modalities that take the balance of inflammation and fungal clearance into account.

Specific challenges to development of mAb-based immunotherapies

The appeal of therapeutic mAbs for infectious diseases is substantial; they augment host immunity, do not induce antifungal resistance or directly affect the microbiome, and provide immediate therapeutic protection regardless of host immune status, thereby overcoming a major limitation of vaccines. Nevertheless, mAb-based therapy poses some unique challenges. In comparison to broadly active antimicrobial drugs, the enhanced specificity of mAbs requires that the identity of the causative microbe be known, and for efficacy, the antibody preparation must be specific to antigenic determinants available on the microbe. Therapeutic antibody is also best administered early in the course of disease. The possibilities of adverse reactions remain; for instance, anti-mAb host immune responses, leading to allergy, infusion-related reactions, compromised immunity, and gastrointestinal- and cardiovascular-related complications, potential toxicity, unexpected pharmacodynamics following administration (Bhatia et al., 2009; Chen and Cleck, 2009; Hansel et al., 2010), and occasional adverse reactions, as observed during Phase-I evaluation of mAb 18B7 (Larsen et al., 2005). Increasingly, however, these concerns are allayed, as rapid diagnosis is now available via various technologies, and it is possible to leverage the mAb technology to produce high affinity antibodies to almost any determinant, while limiting toxicity. Safety profiles of mAb-based immunotherapies are excellent, and potential benefits, significant; therefore, the use of mAbs in treatment and prevention of infectious, including fungal, diseases is a worthwhile pursuit (see discussion in Casadevall and Pirofski, 2015).

AMPs

AMPs are evolutionarily conserved, short endogenous polypeptides that are naturally produced during the innate immune response. They are classified as possible immunotherapeutic agents, because their properties allow them to kill microbes at micromolar concentrations via cytotoxic abilities, including permeabilization and destabilization of the microbial plasma membrane, disruption of metabolic processes, activation of internal processes with lethal consequences, and damage to critical intracellular targets (Zasloff, 2002). The mammalian body secretes AMPs (e.g., defensins, cathelicidins, histone-derived peptide buforin II, etc.) from epithelial cells constitutively and in response to microbes to protect external and internal/luminal surfaces. In

addition, neutrophil-derived AMPs are powerful chemoattractants for CMI components and thereby act as sentinels for adaptive immunity (Zasloff, 2002). However, despite their potential for therapeutic applications (broad spectrum, rapid onset activity, and relatively low possibility of resistance emergence in microbes), development of AMPs as adjunct therapies has faltered mainly because of pharmacokinetics-associated delivery issues (natural AMPs are subject to proteolytic and pH-mediated damage) and significantly high cost of production (Seo *et al.*, 2012). Nonetheless, there are several synthetic and semisynthetic derivatives of natural AMPs under consideration for immunotherapy for fungi, especially as adjuncts to conventional antifungal agents.

AMPs that work through membrane-destabilizing mechanisms include salivary histatins, a family of small cationic histidine-rich AMPs secreted by human salivary glands endowed with plasma membrane-destabilizing/damaging properties by virtue of which they are active against various *Candida* species (*C. albicans*, *C. glabrata*, and *C. krusei*), *Saccharomyces cerevisiae*, *C. neoformans*, and *A. fumigatus* (Tsai and Bobek, 1998; Edgerton and Koshlukova, 2000). One of the most potent Histatins, salivary Histatin-5, induces loss of mitochondrial transmembrane potential in *C. albicans*, triggering free radical generation leading to cell death (Helmerhorst *et al.*, 2001). P-113, a Histatin-5 derivative, has potent broad-spectrum candidacidal activities (*C. albicans*, *C. glabrata*, *Candida parapsilosis*, and *C. tropicalis*) including against azole-resistant strains (Rothstein *et al.*, 2001). Human lactoferrin (hLF) 1-11 is a synthetic AMP, derived from lactoferrin (an innate immunity-associated, iron-binding glycoprotein), which targets *C. albicans* mitochondria and triggers extracellular synthesis and secretion of ATP, which in turn leads to membrane pore formation via surface ATP-binding sites (Lupetti *et al.*, 2000). hLF is active against fluconazole-resistant *C. albicans* and was safe and well tolerated in healthy and bone marrow transplant recipient volunteers (Lupetti *et al.*, 2003; Brouwer *et al.*, 2011). Other lactoferrin-derived synthetic peptides include Lfpep and kaliocin-1, which exhibit fungicidal activity against fluconazole- and amphotericin B-resistant *C. albicans* strains. Kaliocin-1, unlike Lfpep, works via a nonpore forming mechanism that involves an interaction with the microbial mitochondrial membrane (much like Histatin-5) (Viejo-Diaz *et al.*, 2005; Yount *et al.*, 2007). Palmitoyl-lys-ala-DAla-lys is a short synthetic lipopeptide AMP with detergent-like effects and membranolytic activities against *A. fumigatus* in vitro that prolonged survival in an immunocompromised mouse model of aspergillosis (Vallon-Eberhard *et al.*, 2008). Other AMPs include Pleurocidin (an α -helical cationic AMP secreted by the flatfish White Flounder) and its semisynthetic analogs, which has strong candidacidal antifungal activity via disruption of microbial plasma membrane (Jung *et al.*, 2007), and Trappin-2, a neutrophil-derived cationic serine protease inhibitor with strong antifungal activity against *A. fumigatus* and *C. albicans* via disruption of target cell membranes (Baranger *et al.*, 2008). Finally, synthetic peptides that are structurally based on the characterized bactericidal domain of CAP37 (a neutrophil-derived cationic AMP) exhibit significant fungicidal activity against fluconazole-sensitive and -resistant isolates of *C. albicans* blastoconidia, *Candida guilliermondii*, *C. tropicalis*, *Candida pseudotropicalis*, *C. parapsilosis*, and *Candida dubliniensis*. This activity is likely exerted via binding of these AMPs to the fungal membrane through a yet-unidentified receptor leading to membrane disruption (Pereira *et al.*, 2010). In the context of AMPs, special mention must be made of Echinocandins (caspofungin, micafungin, anidulafungin), which are semisynthetic lipopeptides already approved by Food and Drug Administration (FDA) for clinical use as antifungal agents with activity against *C. albicans* and *C. glabrata*, *P. carinii*, *Saccharomyces* and *Aspergillus* species, exerted via fungal cell wall destabilization and lysis due to inhibition of the synthesis of a crucial wall component, $\beta(1,3)$ -D-glucan (Denning, 2003).

The membrane destabilization functions of AMPs depend on their amphipathic nature to facilitate their transmembrane translocation. Thus hydrophobicity is an important physicochemical characteristic that influences their function, and must be taken into consideration during the synthesis of these peptides. For instance, increasing the hydrophobicity of analogs of D-V13K (an α -helical AMP) conferred enhanced antifungal activity against ascomycetes (*Aspergillus nidulans*, *Scedosporium prolificans*, and *C. albicans*), but reduced the activity against zygomycetes (*Absidia corymbifera*, *Rhizopus*, and *Rhizomucor* species). Notably, this increased their general hemolytic effects (Jiang *et al.*, 2008), which is undesirable for clinical applications. On the other hand, for Pleurocidin analogs, reduction in hydrophobicity via polar amino acid substitutions decreased their hemolytic activity, while retaining the antifungal properties (Sung and Lee, 2008).

Some AMPs that work via other distinct mechanisms include the neuropeptide α -melanocyte stimulating hormone (α -MSH) and its synthetic analogs. These peptides are candidacidal via activation of excessive cyclic adenosine monophosphate (cAMP), thereby disrupting the cAMP-mediated signaling pathways essential for *Candida* gene expression. A synthetic analog (CKPV)₂ has excellent activity against the azole-resistant species *C. krusei* and *C. glabrata*, along with significant anti-inflammatory activity via inhibition of TNF α production from host neutrophils (Cutuli *et al.*, 2000; Gatti *et al.*, 2006; Capsoni *et al.*, 2007). Chicken albumen AMP Cystatin is a cysteine-protease inhibitor with fungal growth inhibition effects on azole-sensitive *C. albicans*, *C. parapsilosis*, and *C. tropicalis* comparable to fluconazole. This antifungal activity, distinct from its anti-protease function, is not antagonistic toward azole or polyene antifungals and not vulnerable to efflux-mediated azole-resistance mechanisms in *C. albicans* (Kolaczowska *et al.*, 2010). Synthetic peptide PLD-118 (derivative of naturally occurring β -amino acid, cis-pentacin) inhibits fungal isoleucyl-tRNA synthetase, and thereby, protein synthesis, which led to cessation of growth and significant dose-dependent fungal clearance in an immunocompromised rabbit model of experimental oropharyngeal and esophageal candidiasis with fluconazole-resistant *C. albicans* clinical isolates (Petraitis *et al.*, 2004).

In addition to direct antifungal actions, some AMPs can also work by modulating host immunity. The hematopoiesis-regulating synthetic peptide SK&F 107647 expanded CD11b⁺ monocytes and neutrophils in healthy animals, and significantly reduced organ fungal burden when used in combination with low doses of amphotericin B in persistently neutropenic rabbits with disseminated candidiasis (Lyman *et al.*, 1999). In a mouse model, administration of peptides recognized by T-cells, such as *A. fumigatus* ribotoxin (Aspf1), induced immunological tolerance to *Aspergillus* allergens responsible for ABPA via modulation of cytokine production and reduction in pro-inflammatory responses to *A. fumigatus* (Svirshchevskaya *et al.*, 2000). The spider

hemocyte-derived cationic AMP, gomesin enhanced pro-inflammatory cytokines TNF α , IFN γ , and IL-6 and reduced organ fungal burden in a murine model of disseminated and vaginal candidiasis (Rossi *et al.*, 2012). There are also a host of other small cationic peptides, either induced by IL-6/TNF- α or constitutively expressed, that can modulate cytokine production, alter host gene expression, and/or minimize inflammation (Zhang *et al.*, 2000; Bowdish *et al.*, 2005).

Killer toxins and killer peptides: A functionally different mAb and AMP-based approach

Certain yeasts, described as “killer strains,” secrete protein toxins known as “killer toxins” (KT) with broad-spectrum antimicrobial activity against susceptible (“KT-sensitive”) fungi, bacteria and viruses across wide phylogenetic distances. The secreted toxin interacts with primary and secondary KT receptors (KTRs) on the surface of KT-sensitive microbes, is taken up by endocytosis, and eventually reaches the nucleus where it causes cell-cycle arrest by interfering with DNA synthesis. Alternatively, some toxins disrupt membrane integrity by forming pores (Schmitt and Breinig, 2006). Two such killer yeasts, *Wickerhamomyces anomalus* (formerly known as *Pichia anomala* and *Hansenula anomala*) and *Williopsis saturnus* var. *mrakii* (formerly known as *Hansenula mrakii*), secrete, respectively, PaKT and HM-1 KT. In vivo, two types of antibodies may be generated in response to KT-sensitive fungal species, against the fungal KT and/or against surface KTR, both of which may neutralize KT action by blocking the interaction between KT and KTR. However, anti-idiotypic mAbs (raised against such anti-KT/anti-KTR antibodies) can in turn neutralize these blocking antibodies, thereby permitting KTs to regain their lethal function (reviewed in Magliani *et al.*, 2012) a strategy that has been effective in *C. albicans* (Polonelli *et al.*, 1997). Interestingly, these anti-idiotypic mAbs (which prevent the anti-KT/anti-KTR antibodies from binding to KT/KTRs) mimic the internal structural image of the KTs themselves as reflected in the retention of the KT-like lethal activity against KT-sensitive microbes (Polonelli *et al.*, 2003). As an example, K20, an anti-idiotypic mAb generated against KT-neutralizing mAb KT4, was fungicidal in vitro against KT-sensitive *C. albicans* (Polonelli *et al.*, 2014).

The discovery of naturally occurring anti-idiotypic polyclonal antibodies with KT-like functions (“KT-mimicking antibodies,” KAbs) in the sera of human candidiasis patients that were able to strongly inhibit *P. carinii* attachment to lung cells in murine models (Seguy *et al.*, 1997) corroborated the rationale for the aforementioned “anti-idiotypic” immunotherapy. Since then, monoclonal anti-idiotypic KAbs have demonstrated in vitro and in vivo activity against *A. fumigatus* (Cenci *et al.*, 2002) fluconazole-susceptible or -resistant *C. albicans* (Polonelli *et al.*, 2003), and various *Candida* species (Manfredi *et al.*, 2005). The discovery that cell surface KTR structure may contain β -glucans (β -1,3- and 1,6-glucan) (Polonelli *et al.*, 2003) expanded the scope of KAb activity to phylogenetically distant fungal pathogens, all containing cell wall β -glucans. mAb and recombinant single-chain variable-fragment (scFv) antibodies generated against HM-1 KT also showed significant action against *Aspergillus* (Selvakumar *et al.*, 2006c), *C. albicans* and non-*albicans* species (Selvakumar *et al.*, 2006b) and *Cryptococcus* species (Selvakumar *et al.*, 2006a) via inhibition of β (1,3)-glucan synthase and in *Aspergillus* hyphae, inhibition of metabolic activity (Selvakumar *et al.*, 2006b).

The research on KTs and anti-idiotypic mAbs also led to the discovery of synthetic killer peptides (KPs), a different class of effector AMPs. Derived from the sequence of anti-idiotypic mAb or corresponding scFvs, these KPs retain the functional internal image of the KT and serve as broad-spectrum antifungal molecules. A decapeptide KP fragment P6, derived from the sequence of scFv H6 antibody, retained the ability to bind β -glucan and, therefore, the original candidacidal activity both in vitro and in experimental models of rat vaginal and systemic candidiasis (Polonelli *et al.*, 2003). KP was able to kill a large number of *Candida* strains regardless of their antifungal drug-resistance (Polonelli *et al.*, 2003; Manfredi *et al.*, 2005), *Candida* in biofilms (Manfredi *et al.*, 2007), *P. brasiliensis* (Travassos *et al.*, 2004), and capsular and acapsular *C. neoformans* (Cenci *et al.*, 2004) in vitro and in mice with marked reduction of organ fungal burden and enhanced survival. Interestingly, in addition to direct antifungal activity, KP bound MHC-II and CD16/32 on DCs to modulate expression of MHC-II and pro-inflammatory costimulatory molecules (Cenci *et al.*, 2004, 2006). KP was also active against the fungal phytopathogen *Fusarium oxysporum* (Donini *et al.*, 2005), which can cause disease in neutropenic patients.

Immunotherapy via nonspecific immunomodulation

Cytokine therapy

The principle of nonspecific, adjunctive immune modulation with use of pro- or anti-inflammatory, and/or regulatory cytokines to treat fungal disease is based on the role these mediators play in natural human antifungal immunity. However, as put forth in the DRF, such therapy must establish a balance between pro-inflammatory and anti-inflammatory effects of these mediators to prevent detrimental unresponsiveness or tissue damage from excessive inflammation. This is especially important for a disease like cryptococcal meningitis that can occur in the setting of either a weak/insufficient immune response as in HIV/AIDS or due to the immunosuppressive therapy used for solid organ transplantation as well as in the setting of resurgent immunity due to immune-reconstitution in HIV-infected persons receiving antiretroviral therapy or apparently normal immunity (Datta *et al.*, 2008). In addition, extrinsically introduced cytokines often show synergistic effects with coadministered antifungal agents. Immunomodulatory properties have been demonstrated with various common antifungals, such as polyenes (amphotericin B, nystatin) (Sau *et al.*, 2003; Razonable *et al.*, 2005a,b) azoles (voriconazole) (Simitsopoulou *et al.*, 2008; Salvenmoser *et al.*, 2010), and (as above) echinocandins (caspofungin, micafungin) (Moretti *et al.*, 2012, 2014), in cell lines in vitro and murine models of *A. fumigatus* and *C. albicans* infections. Notably, the toll-like receptors (TLRs) these agents engage under different conditions influence whether pro- or anti-inflammatory cytokines are induced (Simitsopoulou *et al.*, 2008; Salvenmoser *et al.*, 2010; Moretti *et al.*, 2012, 2014). This knowledge, in concert with the tenets of the DRF, makes treatment approaches that combine antifungals and cytokines feasible for certain fungal infections.

Data supporting the use of cytokine-based immunotherapy emanate from research and clinical observations, some of which have been discussed above in the section on CMI-stimulating vaccines. IFN γ , the prototypical pro-inflammatory cytokine released from CD4⁺ and CD8⁺ T-cells and NK cells, is an important candidate due to its ability to induce Th1-mediated antifungal immunity and activate effector phagocytes to exert fungicidal effects. Therapeutic use of IFN γ is supported by the observations that candidiasis and aspergillosis, fungal diseases with different pathogenesis, are each susceptible to Th1-type, especially IFN γ -mediated responses (Netea *et al.*, 2003; Chai *et al.*, 2010), and that Th1-immunity to *A. fumigatus* is cross-protective with *C. albicans* (Stuehler *et al.*, 2011). In addition, there is some clinical evidence for a benefit of IFN γ in invasive fungal infections (Hubel *et al.*, 2002) especially in immune-suppressed populations. For example, in a clinical trial in patients with invasive candidiasis and/or aspergillosis, adjunctive immunotherapy with recombinant IFN γ (in conjunction with an echinocandin) improved leukocyte immune responses via upregulation of HLA-DR expression and enhancement of pro-inflammatory cytokines associated with both innate and adaptive immunity (Delsing *et al.*, 2014). In HIV-associated cryptococcal meningitis, short-term combination therapy with IFN γ with amphotericin B markedly enhanced clearance of *C. neoformans* from the brain with minimal adverse effects (Jarvis *et al.*, 2012). In addition, IFN γ levels in cerebrospinal fluid correlated positively with treatment outcome (Siddiqui *et al.*, 2005; Jarvis *et al.*, 2015; Mora *et al.*, 2015) and negatively with detrimental immune-reconstitution inflammatory syndrome (IRIS) (Chang *et al.*, 2013a). Also, adjunctive IFN γ in association with antifungals showed encouraging results, including in salvage therapy of refractory disease (Pappas *et al.*, 2004; Gamaletsos *et al.*, 2012).

In addition to IFN γ , granulocyte (G) and GM-CSF have received attention as adjunctive therapy to modulate antifungal immunity, with the caveat that data on their clinical use are largely restricted to small studies or case reports. G-CSF and GM-CSF are of particular interest, since their ability to reduce/reverse neutropenia and enhance functions of neutrophils and macrophages (Georgopapadakou and Walsh, 1996) is likely to be beneficial in fungal infections where phagocytosis and inflammatory mechanisms are required for defense. Encouraging results in vitro and in animal models have provided the rationale for human use (Chiou *et al.*, 2000; Hubel *et al.*, 2002). In HIV-positive children, antifungal function of neutrophils against *A. fumigatus* hyphae (which is diminished in HIV infection, even in absence of neutropenia) was restored via ex vivo stimulation with G-CSF (Roilides *et al.*, 1993). Used in conjunction with azole antifungals, recombinant G-CSF and GM-CSF both enhanced candidacidal activity of neutrophils and monocytes in vitro (Vora *et al.*, 1998). In a clinical trial with HIV-positive patients, recombinant human GM-CSF as adjunct therapy showed encouraging results in fluconazole-refractory oropharyngeal candidiasis (Vazquez *et al.*, 2000). GM-CSF was shown to help maintain pro-inflammatory IL-1 α , TNF α , and macrophage inflammatory protein (MIP)-1 α responses of mouse bronchoalveolar macrophages challenged with *Aspergillus* conidia in vitro (Brummer *et al.*, 2003), and, in a murine model of pulmonary aspergillosis, intranasally administered GM-CSF increased macrophage activation and reduced lung fungal burden (Quezada *et al.*, 2008). In an interesting case, long-term, continuous treatment with intravenous GM-CSF followed by short-term subcutaneous G-CSF in a diabetic patient with isolated chronic mucocutaneous candidiasis resulted in complete remission, improvement in monocyte and neutrophil functions, along with stimulation of Th17 cells (including CD4⁺CD8⁻TCR $\gamma\delta$ cells) and suppression of inappropriate IFN γ secretion (Wildbaum *et al.*, 2013). Recently, a case of relapsing *C. albicans* meningoencephalitis in the setting of primary immunodeficiency associated with a genetic defect in Th17 immunity and defective IL-17 and IFN γ synthesis achieved complete remission and improvement in IL-17 secretion with G-CSF treatment (Celmeli *et al.*, 2016).

Promising results have also been seen with pro-inflammatory cytokines (such as IL-12 and IL-17) in both in vitro and mouse models of various fungal infections. Protective effects of IL-12 treatment (mediated by IFN γ) were demonstrated in mice infected with *H. capsulatum* (Zhou *et al.*, 1995) and *C. neoformans* (Decken *et al.*, 1998). Another Th1 cytokine, IL-18, was shown to work in close conjunction with IL-12 and IFN γ to protect mice against disseminated cryptococcosis (Antachopoulos and Walsh, 2012). Treatment of *Coccidioides immitis*-challenged mice with recombinant IL-12-secreting J774 macrophages protected the mice by reducing organ *C. immitis* burdens and stimulating secretion of IFN γ (Jiang *et al.*, 1999). Immunocompetent mice responded to *P. carinii* challenge by releasing IL-12, and exogenously administered IL-12 enhanced *P. carinii* clearance via inflammatory cell recruitment into lung tissue with release of IFN γ , TNF α , and IL-12 in immunocompetent and CD4⁺ T-cell depleted mice (Ruan *et al.*, 2008).

CD4⁺ Th17 cells elicit IL-17, IL-21, and IL-22 function that bridges innate and adaptive immunity to mucosal infections (Khader *et al.*, 2009). IL-17 mediates protection against various bacteria and fungi via induction of CMI mediators (such as G-CSF, IL-6, and IL-8/CXCL8), neutrophil differentiation and migration, and AMPs, such as β -defensins and S100As see above, and reviewed in Matsuzaki and Umemura (2007) and Khader *et al.* (2009). The recent discovery of a genetic predisposition to chronic mucocutaneous candidiasis (Huppler *et al.*, 2012) has led to the recognition of the role of IL-17 in resistance to mucosal fungal infections. Human diseases linked to IL-17 signaling defects that lead to reduced IL-17 and Th17 impairment have been associated with autoantibodies, mutations in the IL-17 gene or its receptor, and other mutations (e.g., in STAT-3, responsible for autosomal dominant hyper-IgE syndrome) (reviewed in Khader *et al.*, 2009; Huppler *et al.*, 2012). In murine respiratory *P. carinii* and *A. fumigatus* infection models, early induction of IL-17 (along with IL-23, which drives lineage commitment of Th17 cells) plays a pivotal role in fungal clearance (Rudner *et al.*, 2007; Werner *et al.*, 2009). Notably, and important in the context of the DRE, IL-17 modulates the expression and/or pro-inflammatory properties of IL-22 to protect against acute tissue damage at mucosal sites and in the lungs following various infectious and other pathological conditions (Sonnenberg *et al.*, 2010). The critical importance of this modulation is highlighted by the observation that heightened and persistent Th17 responses driven by dendritic cell-derived IL-23 are responsible for inflammatory host tissue damage via neutrophils in murine models of candidiasis and aspergillosis, with no concomitant restriction of fungal growth (Zelante *et al.*, 2007). The balance between protective and inflammatory effects of

T_H17 cells is under intense research, and data indicate that T_H17 mucosal immunity may need further downstream regulators to achieve this outcome (Khader *et al.*, 2009).

Preclinical in vitro and in vivo murine studies have demonstrated the promise of a few other cytokines against fungal infections. In a murine model of *C. albicans* sepsis, IL-7 (a pluripotent cytokine that induces proliferation and activation of naïve and memory T-cells) increased lymphocyte function (including expression of adhesion molecules and IFN γ production), DTH responses, and host survival (Unsinger *et al.*, 2012). TNF α (closely associated with IL-12/IL-18) was beneficial in a murine model of disseminated cryptococcosis (Kawakami *et al.*, 1999). Notably, the potential importance of TNF α is further highlighted by the observed increase in risk for fungal disease during treatment with TNF α antagonists (such as the mAbs infliximab or adalimumab), or the anti-inflammatory TNF receptor Fc fusion protein etanercept (Weinblatt *et al.*, 1999). Patients who received a TNF inhibitor (TNFi) had an increased incidence of *Pneumocystis jirovecii* (human variant of *P. carinii*) pneumonia and other fungal infections (Chirch *et al.*, 2014; Grubbs and Baddley, 2014). In an ex vivo cell culture system, the type 1 cytokine IL-2-activated fungistatic and fungicidal activities of T-cells (CD4⁺ and CD8⁺), T-lineage NK cells, and CD16⁺/56⁺ non-T-lineage NK and LAK cells against encapsulated *C. neoformans* (Levitz and Dupont, 1993), and a combination of an anti-CD40 antibody (CD40 is a member of TNF α receptor family) and IL-2 (mediated via IFN γ) was protective in murine cryptococcal infection (Zhou *et al.*, 2006, 2007).

Immunotherapy of rare mold infections via immunomodulation

Certain molds, including the septate, filamentous sordariomycetes *Fusarium* and *Scedosporium*, non-septate zygomycetes (such as *Rhizopus* and *Mucor*), and certain yeast different from *Candida* and *Cryptococcus* (such as *Trichosporon*), have emerged as important causes of high morbidity and mortality in patients undergoing myeloablative therapy and/or stem cell/bone marrow and/or solid organ transplantation (Katragkou and Roilides, 2012). Conventional antifungal therapies are often of extremely limited efficacy in diseases caused by molds, in large part because these agents are unable to eradicate the causative fungus in the setting of severely impaired immunity. Therefore, approaches that augment host immune responses via immunotherapy make sense, with the caveat (usual for this modality) that not all such methods have been tested in randomized clinical trials (reviewed in Katragkou and Roilides, 2012). Nevertheless, these examples provide hope that understanding of the pathophysiology of disease pathogenesis can be leveraged to direct immunotherapy. For instance, given the clinical importance of host neutropenia in development of zygomycosis, transfusion of granulocytes stimulated by recombinant G-/GM-CSF or IFN γ has shown promise in research (in vivo) models and limited clinical cases, alone or in conjunction with conventional antifungals. Notably, the lipid-lowering drug group, statins, also appear to have broad-spectrum and pleiotropic abilities to modulate immune and inflammatory functions and are fungicidal against zygomycetes, albeit with variable modes of action and fungal susceptibilities (see Katragkou and Roilides, 2012). Similarly, stimulation of neutrophils with IFN γ , GM-CSF, and/or IL-15, as well as granulocyte transfusion, has shown beneficial effects (in research models and isolated clinical cases) against *Scedosporium* and *Fusarium*, both fungi with relatively high innate resistance to administration of antifungals alone (Katragkou and Roilides, 2012).

The importance of negative immunomodulation as therapy for fungal infections

The DRF underscores an important principle of microbial pathogenesis, namely, that host–microbe interaction can lead to host tissue damage (the hallmark of “disease”) stemming from an exuberant and unmodulated host inflammatory response. Excessive inflammation has been observed in the central nervous system of otherwise normal patients with *C. gattii* (Panackal and Williamson, 2015), and dysregulated inflammation has been implicated in the pathogenesis of ART-induced *Cryptococcus*-associated IRIS (Chang *et al.*, 2013a; Eschke *et al.*, 2015; Jarvis *et al.*, 2015; Panackal and Williamson 2015; Kao and Goldman 2016). Along the same lines, excessive inflammation has been implicated in various manifestations of candidiasis (see Jabra-Rizk *et al.*, 2016). In such situations, adjunct therapeutic interventions that dampen the inflammation in a generalized or targeted manner may be beneficial.

Adoptive cell transfer

For the past two decades, numerous in vitro and ex vivo studies have evaluated various strategies to prime, enhance, or modulate the antifungal immunity afforded by components of innate and adaptive CMI, such as granulocytes, DCs, NK cells, lymphokine-activate killer (LAK) cells, and CD4⁺ or CD8⁺ T-cells. For instance, adoptive transfer of Th1-committed CD4⁺ T-cells (secreting IFN γ and IL-2) from mice immunized with crude antigen from *A. fumigatus* conferred protection to neutropenic naïve mice against aspergillosis (Cenci *et al.*, 2000). Similarly, upon adoptive transfer, cytotoxic CD8⁺ T-cells generated against *Aspergillus* peptide antigen f16 (Aspf16) increased the survival time of *A. fumigatus*-infected immunocompromised mice (Sun *et al.*, 2012). In allogeneic bone marrow transplant recipients with IA, adoptive transfer of donor-derived anti-*Aspergillus* T_H1 cells, generated via ex vivo exposure of donor T-cells to *Aspergillus* antigens in a CMI context, conferred immunity to recipients and the T_H1 cells retained their proliferative abilities. However, it was also observed that commonly used immunosuppressants, such as cyclosporin A, mycophenolic acid, glucocorticoids, and rapamycin reduced the overall numbers of anti-*Aspergillus* T_H1 cells, raising concerns about the utility of this modality for organ transplant recipients (Tramsen *et al.*, 2014). Adoptive T-cell transfer has also shown promise in experimental murine infections with dimorphic fungi. Administration of *Histoplasma*-reactive CD4⁺ T-cells followed by pulmonary challenge with *H. capsulatum* reduced the fungal tissue burden of nude C57BL/10 mice or irradiated heterozygous nude (nu/+) C57BL/6 mice (but not normal or neutropenic mice) (Allendoerfer *et al.*, 1993), and adoptive transfer of IFN γ -producing CD4⁺ T-cells expressing V α 2⁺J α 49⁺/V β ⁺J β 1⁺ TCR generated against cell wall/membrane components of *B. dermatitidis* protected against lethal experimental murine blastomycosis (Wuthrich *et al.*, 2007).

APCs, such as multifunctional DCs, play a key role in bridging innate and adaptive immunity against fungi. Pulsing human or murine DCs with live fungal components (*Aspergillus* conidia or hyphae) or RNA derived from these components led to their functional maturation. Such mature DCs-activated antigen-specific, IFN γ -secreting T-cells in situ and upon adoptive transfer to naïve mice, contributed to rapid recovery of immunocompetence in mice receiving allogeneic bone marrow transplants with experimental aspergillosis (Bozza *et al.*, 2003). Similarly, priming DCs and other APCs with pentadecapeptides (PPCs) spanning the Asp f16 coding sequence expanded the APC pool and generated potently cytotoxic T-cells (Ramadan *et al.*, 2005; Zhu *et al.*, 2008), with the ability to kill *Aspergillus* conidia and DCs pulsed with Asp f16-PPC or *Aspergillus* culture-extract (Ramadan *et al.*, 2005). Autologous DCs, pulsed with conidial lysates from an *A. fumigatus* environmental strain and cocultured with neutrophils in presence of IL-2, IL-7, and IL-15, resulted in a >30-fold increase in effector and memory CD4⁺ T cell numbers (Gaundar *et al.*, 2012). Because these adoptive transfer strategies exhibit secondary effects upon recipient effector cells that induce activation, such transfers are often equated with vaccinations. However, by virtue of their inherent functional plasticity, certain subsets of DCs are also able to modulate and dampen exuberant inflammatory responses via T_{reg} induction (Perruccio *et al.*, 2004).

Granulocytes, including neutrophils, are crucial effector cells in antifungal immune defense. Invasive fungal infections often occur in the setting of neutrophil dysfunction or frank neutropenia (a common presentation of many hematological disorders and a known complication of cancer chemotherapy) and are associated with high mortality under such conditions despite appropriate antifungal therapy (Hubel *et al.*, 2001). Transfusion of granulocytes ("GTX") from healthy donors, stimulated by G-CSF or steroids, in conjunction with antimicrobial therapy was shown to improve clinical outcome in neutropenic patients with various infectious diseases, including IA and *Candida* sepsis, when administered therapeutically (Hubel *et al.*, 2001; Illerhaus *et al.*, 2002) or as prophylaxis for neutropenic patients at risk for invasive fungal infections (Illerhaus *et al.*, 2002; Kerr *et al.*, 2003); also see this Cochran meta-analysis (Estcourt *et al.*, 2015). The feasibility, tolerance and efficacy of combination of antifungal-GTX was demonstrated in several clinical studies in neutropenic pediatric and young adult patients with cancer and history of proven mold or yeast infections (Grigull *et al.*, 2006a,b; Sachs *et al.*, 2006; Seidel *et al.*, 2009). G-CSF-activated GTX reconstituted absolute neutrophil counts and effectively cleared *Zygomycete* infections (Pagano *et al.*, 2009). In patients with severe aplastic anemia, GTX administered in conjunction with G-CSF improved survival rates from fungal infections (aspergillosis, cryptococcosis, and candidiasis) and hematopoietic recovery (Wang *et al.*, 2014a,b). GTX has been shown to result in significant clinical improvement in invasive fusariosis, a disease relatively refractory to available antifungals; however, the efficacy was much reduced if the neutrophil recovery was hampered due to underlying conditions (Kadri *et al.*, 2015). In this chapter, the decrement in neutrophil response to GTX was attributed to HLA alloimmunization (Kadri *et al.*, 2015), which remains an important concern in the otherwise well-tolerated GTX modality (for a discussion of concerns, see Hubel *et al.*, 2001). Commonly occurring mild and manageable reactions to GTX aside, this modality can lead to more severe side effects, including hypotension and acute lung injury, whose mechanism is poorly understood. A more critical, potential complication is alloimmunization or graft-versus-host disease (GVHD) secondary to GTX; however, irradiation of GTX products prevents GVHD, and alloimmunization appears to be a problem only in case of underlying neutrophil dysfunctions. Prophylactic GTX prior to bone marrow transplants may cause delayed engraftment if the granulocytes are sourced from an incompatible donor; however, a lymphotoxicity assay prior to GTX may establish donor compatibility (Hubel *et al.*, 2001). Therefore, even though the therapeutic potential of GTX has not yet been proved in controlled clinical trials, this modality appears to hold promise as a safe, low-toxicity and efficacious option to protect neutropenic patients from invasive fungal diseases.

In addition to granulocytes, two other cell types tested in studies were: (1) HL-60, a human myeloid, phagocytic cell line derived from a cancer patient, and (2) mesenchymal stem cells/MSCs, which are multipotent, non-hematopoietic progenitor cells that can differentiate into multiple lineages, and have excellent proliferative potential, low immunogenicity, and immunomodulatory properties. HL-60 cells can be activated to differentiate toward a mature neutrophil phenotype, and administration of activated, irradiated HL-60 cells improved the survival of neutropenic mice with candidemia (Spellberg *et al.*, 2007). In murine models, MSCs have shown promise for treatment of liver fibrosis and hepatocarcinoma as well as bacterial infections and allergic airway inflammations, and may show promise for fungal diseases also. A single colony-derived IL-17-producing subset of bone marrow MSCs inhibited *C. albicans* growth in vitro and promoted survival of mice with candidiasis (Yang *et al.*, 2013). In an in vitro study with a murine macrophage cell line J774A.1, murine bone marrow MSCs exerted anti-inflammatory effects by decreasing TNF α and increasing IL-10 elicited by macrophages in response to *A. fumigatus* conidia, and also reduced fungal growth (Cho *et al.*, 2016).

Other immune effector cell lineages, including NK cells, monocytes and B-cells, have been evaluated for their protective potential via adoptive transfer. Human NK cells inflict direct damage to *A. fumigatus* cells via release of IFN γ , a mechanism that is separate from NK cytotoxicity stemming from toxic proteins (Bouzani *et al.*, 2011). Bacillus Calmette-Guerin (BCG)-vaccination in healthy volunteers helps generate trained immunity in NK cells, which may react with non-related non-mycobacterial microbes. BCG-induced trained NK cells enhanced the survival of SCID mice with disseminated candidiasis (Kleinnijenhuis *et al.*, 2014). C-C chemokine receptor 2 (CCR2)- and Ly6C-expressing inflammatory monocytes are effectors involved in the response in systemic candidiasis during active infection; in mice depleted of CCR2, adoptive transfer of such monocytes early in the infection promotes fungal clearance from kidney and brain (Ngo *et al.*, 2014). In mice lacking lymphocytes due to type-I IFN receptor deficiency (IFN γ ^{-/-}), adoptive transfer of B-cells helped maintain early hematopoietic progenitor activity during immune response to *Pneumocystis* infection and replenished the bone marrow in an IL-10- and IL-27-dependent manner (Hoyt *et al.*, 2015).

Table 2 Features of antifungal immunotherapy approaches

Modality	Type	Specificity	Mechanism(s) of action	Advantages	Concerns
Active	vaccine	Host	1. Induces fungus-specific adaptive immune response 2. Generates immunological memory 3. Acts via antibody-mediated and cellular effector mechanisms 4. Has the potential to act therapeutically, either to limit damage from reactivation of latent fungal infection or to augment fungal clearance in an ongoing or reactivated infection	1. Ample research, clinical data, and success with vaccines for other microbes support the approach 2. Independent, overlapping and/or redundant mechanisms are harnessed to produce comprehensive immunity 3. Has the potential to induce broad spectrum (multi-strain/microbe) activity 4. May work even in certain settings of immune suppression	1. Poor immunogenicity and/or immunosuppressive properties of certain fungal antigens (rational vaccine design and right adjuvants may help) 2. May require immune competence to be effective (rational vaccine design and right adjuvants may help) 3. May induce pathogen strain replacement (unlikely for conserved fungal determinants) 4. Cost, disbelief, and nonscientific impediments to development
Passive	mAbs	Fungus	Direct and indirect antifungal activities, including: 1. Neutralization and/or blocking of fungal antigens 2. Opsonization of fungal cells 3. Complement- and antibody-dependent cytotoxicity 4. Direct membrane damage leading to cellular lysis 5. Alterations in gene expression	1. Supported by robust preclinical data that has demonstrated antibody-mediated immunity be beneficial in host defense against fungi 2. Direct and indirect action, dependent on or independent of host immune status 3. Immediate action 4. Enables next-generation modalities, for example, radioimmunotherapy 5. Narrow spectrum of activity 6. Excellent safety profile	1. Narrow spectrum of activity, requiring fungal etiology to be identified before therapy (advances in molecular biology assist in rapid production of specific mAbs) 2. Early administration required for maximum efficacy (better diagnostic options may help) 3. Possibility of adverse reactions 4. Nonscientific issues hampering development
		Host	Immunomodulation, polarization of effector cells, repopulation of specific cell subsets		Balance of pro-inflammatory action and fungal clearance is an important consideration
Passive	AMP	Fungus	1. Direct cytotoxic activity via membrane destabilization, disruption of cellular metabolism, and signaling cascades 2. Chemoattractants for adaptive immune effectors	1. Endogenous products of innate immune response 2. Effective at small concentrations 3. Broad spectrum 4. Rapid onset activity 5. Relatively low possibility of resistance emergence in fungi 6. May act synergistically with antifungals	1. Pharmacokinetics-associated delivery issues 2. High cost of production
		Host	Immunomodulation		
Passive	KT, KP	Fungus	Similar to mAbs (KT) and AMP (KP)	Effective in in vitro, and in vivo preclinical models against yeasts and molds	Narrow spectrum of activity, difficult to produce, paucity of data
Passive	Cytokine therapy	Host	1. Nonspecific, adjunctive immune modulation 2. Pro-, anti-inflammatory and regulatory functions 3. Mobilization of effector immune response against fungi	1. Leverages the natural immune functions of these molecules 2. May act synergistically with antifungals 3. Benefits seen in isolated clinical cases	1. May cause excessive inflammation, tissue injury, or induce tolerance (can be carefully calibrated to achieve balance) 2. Paucity of data
	Adoptive cell	transfer	Host	Repopulation of immune subsets following ex vivo activation (effective especially in case of cellular immune defects in recipients)	1. Leverages the natural immune functions of these effector cells 2. Modulates immune responses to fungal antigens 3. Benefits seen in isolated clinical cases and in clinical trials – safe, low-toxicity, efficacious

Table 2 Continued

Modality	Type	Specificity	Mechanism(s) of action	Advantages	Concerns
			Possibility of severe side effects, alloimmunization and graft vs. host disease (can be clinically managed)		

Abbreviations: AMP, antimicrobial peptide; KT, killer toxin; KP, killer peptide; mAbs, monoclonal antibodies.

Fungal allergy and immunotherapy

Mold allergens are spores and/or submicron-size mycelial fragments from filamentous fungi, such as *Alternaria*, *Cladosporium*, *Penicillium*, and *Aspergillus*, up to 28 fungal genera, that elicit 107 variants of allergens. They are ubiquitous, and significant etiological agents of respiratory allergy, rhinitis and asthma. These allergens, mostly proteins (enzymes, Hsps, and peroxisomal proteins), are capable of inducing strong IgE- or T-cell mediated inflammatory reactions and, therefore, are potential candidates for use in immunotherapy to suppress inflammatory pathways or induce antigen-specific responses that modify disease progression (Twaroch *et al.*, 2015). However, severe adverse reactions from mold extracts in early studies hindered the development of efficient immunotherapies. A promising targeted approach used allergen-DNA transfected DCs to generate allergen-specific IgG4 but not IgE, and stimulated autologous CD4⁺ and CD8⁺ T-cells to secrete Th1 cytokines (Konig *et al.*, 2007). Newer approaches, such as recombinant hypoallergenic allergen derivatives (with IgE epitopes deleted or host IgG generated to neutralize allergen IgE epitope) and peptide-based allergen vaccines (with targeted mutations to lower IgE binding), aim to induce tolerance to the allergen by reducing IgE production, downregulating Th2-mediated responses, and generating more T_{reg} cells (Twaroch *et al.*, 2015). Chronic inflammation associated with allergic fungal sinusitis does not respond well to standard treatment options, but has been amenable to adjunct sublingual immunotherapy (drops of allergens in metered, sublingual doses), which lowers serum IgE levels with no adverse effect (reviewed in Melzer *et al.*, 2015).

Concluding Remarks

Notwithstanding the availability of antifungal agents, the burden of invasive mycoses, especially in immunity-impaired populations, demands the exploration of new approaches to prevention and treatment. Human antifungal vaccines and other immunotherapies would represent a significant step in that direction. The promise of immunotherapy for fungal diseases lies in the ability of this modality to leverage the host immune response to achieve a beneficial effect that induces fungal clearance and/or modulates the inflammatory response to limit host damage (summary in Table 2). Although various circumstances have hindered the progress of developmental efforts, the advent of new technologies, platforms to dissect the immune response, and rapid diagnostics make the prospect of active and/or passive immunotherapy for fungal diseases eminently logical and feasible. Vaccines for a wide variety of microbial infections have a long track record of safety, success globally, and economic benefit. Therefore, management of mycotic diseases via vaccines and other immunotherapeutic interventions deserves vigorous consideration and support. Advances in our understanding of fungal pathogenesis have revealed previously unappreciated opportunities to influence the immune response to the benefit of the host with fungal disease. Continued research into host–fungus interactions in the pathogenesis of fungal disease holds the key to the development of specific and nonspecific immunotherapeutic modalities to treat fungal disease in the future.

Glossary

Antigen A molecule capable of inducing an immune response in the host organism.

Commensal fungi Fungal species that live in or within human body without harming or affecting it.

Complement fixation A diagnostic test which is based on the process of binding serum complement to the product formed by the union of an antibody and the antigen for which it is specific.

Cross-reactivity (of a antigen detection method) When an antibody directed against one specific antigen is successful in binding with a different antigen.

Differential diagnosis The differentiation between two or more conditions which share similar symptomatology.

Endemic mycoses Mycoses caused by fungal species that have specific geographic distributions such as *Histoplasma capsulatum*, *Paracoccidioides* spp., *Coccidioides* spp., and *Blastomyces dermatitidis*.

Environmental fungi Fungal species that are commonly present in the environment.

Enzyme Immune Assay (EIA) A test that measures the presence or concentration of a molecule in a solution through the use of an antibody or an antigen, which is linked to an enzyme. These enzymes allow for detection because they produce an observable color change or light in the presence of certain reagents.

EORTC/MSG criteria A standard set of definitions of invasive fungal disease which aim is to improve the quality of clinical studies. These criteria have been established by the Mycoses Study Group of the European Organization for Research and Treatment of Cancer and the National Institute of Allergy and Infectious Diseases.

False negative (of a diagnostic test) A negative result given by the test that actually is positive.

False positive (of a diagnostic test) A positive result given by the test that actually is negative.

Immunodiffusion A diagnostic test which involves diffusion of the antigen and the antibody through a substance such as agar. The antigen and the antibody bind with each other and form an insoluble immuno-precipitate.

ITS region Internal transcribed sequence region of the ribosomal DNA that has been classically used for the identification of fungal species.

Latex-agglutination A diagnostic test for the detection of antigens or antibodies in a sample. When a sample containing the specific antigen (or antibody) is mixed with an antibody (or antigen) which is coated on the surface of latex particles, a visible agglutination occurs.

MALDI-ToF MS technology Matrix-assisted laser desorption ionization time of flight mass spectrometry is an identification method based on the acquisition of a mass spectrum from an unknown microorganism and its comparison with a database of reference spectra to determine the organism identity.

Opportunistic fungal infections Infection by a fungus that normally does not cause disease but becomes pathogenic when patient's immune system is impaired and unable to articulate a response to the infection.

Point of care (POC) diagnostic method Medical testing at or near the site of patient care. These methods are characterized for being simple, fast, and cheap.

Polymerase chain reaction (PCR) A laboratory molecular technique used to make multiple copies of a segment of DNA.

Sensitivity (of a diagnostic test) The proportion of true positives that are correctly identified by the test.

Specificity (of a diagnostic test) The proportion of true negatives that are correctly identified by the test.

Introduction

Human fungal infections encompass a broad spectrum of diseases caused by more than 600 species of fungi present in the environment (see "Relevant Websites section"). They can affect any part of the body producing superficial infections (skin and nails), mucosal infections, chronic and allergic infections, and finally, they also can invade tissues causing an invasive fungal infection (IFI). IFI is the most serious clinical entity with a high mortality since mainly affect immunosuppressed patients with poor general condition.

Diagnosis of these diseases is difficult and frequently delayed due to the lack of suspicion and/or the lack of suitable diagnostic tests. In many parts of the globe, particularly in low income countries, some of these infections are neglected diseases than could be easily solved with skilled personnel and adequate diagnosis (Oladele et al., 2019). In developed countries, the main problem is that these invasive infections occur in highly immunosuppressed patients with a poor outcome in absence of an early diagnosis. The increasing use of immunosuppressive drugs for treating serious medical conditions have favored the rise of opportunistic fungal infections in these regions.

The overall mortality due to fungal infections is around 1,600,000 people per year (Bongomin et al., 2017). The most common species involved in invasive disease are *Aspergillus* spp. *Candida* spp. *Cryptococcus* spp., *Pneumocystis jirovecii* and fungi responsible of

Fig. 1 Main human fungal infections and the corresponding laboratory techniques commonly used for their diagnosis.

endemic mycoses (*Histoplasma capsulatum*, *Paracoccidioides* spp., *Coccidioides* spp., and *Blastomyces dermatitidis*). Nevertheless, when a patient has several predisposing factors for a prolonged period of time, almost any fungal species can cause an infection.

The clinical profile of mycosis varies greatly depending on the causal agent, the location of the infection, and the predisposing factors of the patient. Regardless of the patient's clinic, the diagnosis is always difficult. Classical diagnosis methods have limitations as they lack of a suitable sensitivity and specificity. Recently, new diagnostic tests have been developed but many of them are still used in combination with classical methods because of the lack of validation and consensus among laboratories. Moreover, some of these new techniques are too expensive for resource challenging countries. This review describes the methods routinely employed in the Mycology Laboratories and their usefulness in the diagnosis of the different clinical entities in the field of the Medical Mycology. In addition, it delves into the methods most recently developed and describes their use alone or in combination with classical methods.

Two figures have been included with the purpose of summarizing all these concepts. In **Fig. 1** it is shown how, depending on the kind of infection, the number of techniques used is greater and more specialized due to both the difficulty of the diagnosis and the severity of the infection. In **Fig. 2**, a brief summary of all diagnostic techniques that can be performed has been presented.

Conventional Diagnostic Methods

Conventional diagnostic methods are those used classically in the Laboratory of Microbiology. Although they are useful, they lack of sensitivity and specificity and should be used in combination with the new tools recently developed.

Culture

Isolating the fungus from a clinical sample using an adequate culture medium is considered the gold standard method for the diagnosis of a fungal infection. Specific media for fungal culture commonly used are Sabouraud dextrose agar (SDA), potato dextrose agar (PDA), malt extract agar (MEA), and, less commonly, brain heart infusion (BHI). Optimally, cultures should be incubated at 30°C ($\pm 1^\circ\text{C}$) during 7 days, but some fungal species require longer incubation periods, up to several weeks (Sutton, 2015). Although this technique is simple and cheap, it is time consuming and its diagnostic performance depends on sample origin, fungal species, underlying disease of the patient, clinical status, etc. Here we cite some examples: (1) Blood cultures, which has been used mainly in *Candida* spp. invasive infections, are frequently negative in other infections even if they are disseminated (Alexander and Pfaller, 2006), (2) Mucorales species are fast growing but the yield in cultures from clinical samples is low, probably due to the fragility of their hyphae (Ribes et al., 2000), (3) endemic fungi are fastidious and slow-growth organisms that requires 3–4 weeks to

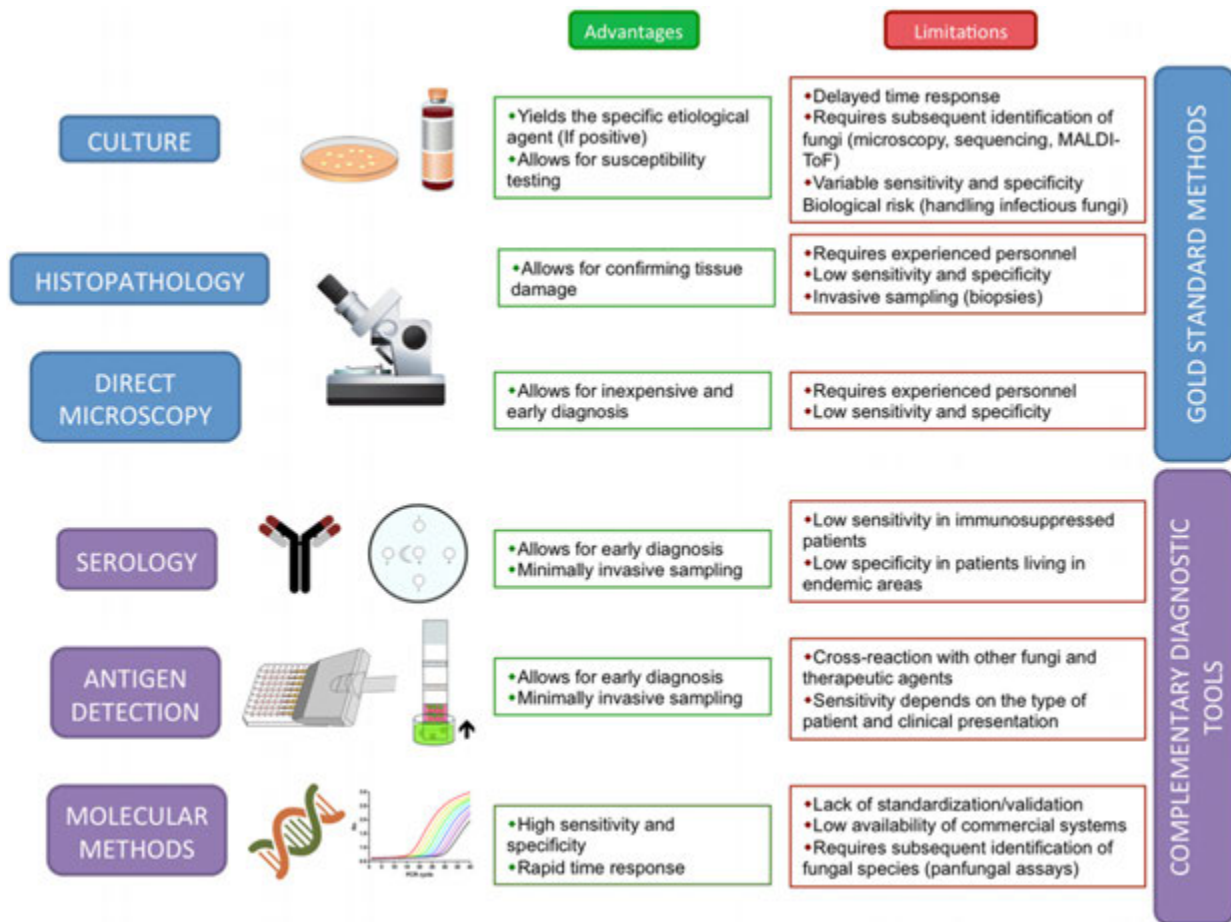

Fig. 2 Advantages and limitations of both classical and new fungal diagnostic methods.

growth (Buitrago *et al.*, 2011), etc. Finally, false positive results are common since fungi are usual contaminants of the laboratory and part of the saprophytic human flora (Cuenca-Estrella *et al.*, 2008).

Once the culture is obtained, the identification of the grown fungus is essential, especially in invasive disease, in order to establish an appropriate antifungal therapy. Classical fungal identification requires the visualization and identification of the different fungal structures by microscopy. In the case of yeasts, also biochemical tests of carbon assimilation and/or fermentation are carried out to complement microscopical observations (Willinger *et al.*, 2015). Microscopical identification requires very skilled and specialized personnel that can be common in a reference center but rare in a clinical setting. Recently, however, a fast identification is possible by using alternative techniques such as those based on mass spectrometry (MS) or molecular methods. In the last decade, MALDI-TOF technology has revolutionized microbial identification since it is easy to use and allows reducing costs as well as time response (Posteraro *et al.*, 2013). The sequencing of specific DNA targets, mainly the ITS region of the ribosomal has been very useful for identification of fungi and taxonomical studies being considered the gold standard method for fungal molecular identification (Perlin and Wiederhold, 2017) but this specialized approach is time consuming and requires an appropriate database for sequence comparison (Irinzi *et al.*, 2015).

Direct Visualization and Histopathology

Direct examination of clinical samples by microscopy to detect fungal structures is also a simple, cheap, and rapid method largely used in Microbiology laboratories. Samples are visualized after being treated with KOH 10% or stained with specific dyes. It is a very useful technique for some species as *Pneumocystis jirovecii* (immunofluorescent staining) (Tasaka and Tokuda, 2013) or *Cryptococcus neoformans* (Indian ink staining) (Baddley and Dismukes, 2011), but in general, it lacks sensitivity and negative results never rule out an infection by fungi.

Histopathology uses tissue samples to identify fungal structures by microscopy. If fungi are suspected, the specimens are first colored with stains that highlight the fungal wall as Gomori methenamine silver (GMS) or periodic acid-Schiff (PAS). This method, although is an important tool for the microbiologist, has also several limitations. Moreover, obtaining biopsies

of the affected tissue is a very invasive procedure and may be contraindicated in certain patients (Guarner and Brandt, 2011; Perfect, 2013). In other cases, the amount of material obtained is very limited making histopathological studies impossible.

Both methods enable the identification of fungal structures and they can provide a presumptive diagnosis while waiting for additional test for identifying the species involved, as the presence of common fungal elements such as hyphae or yeasts in samples or tissues does not provide sufficient information to identify the species (Lease and Alexander, 2011). The sensitivity for microscopic morphological techniques have been reported that varies from 20% to 80% (Guarner and Brandt, 2011). Finally, very skilled personnel is required for both methods as it is difficult to identify fungal structures in tissues and misidentifications are frequent. Diagnosis by these methods should be descriptive and correlated with clinical and epidemiological data.

New Diagnostic Methods

To overcome weaknesses of conventional diagnostic methods, alternative approaches based on the detection of antibodies, antigens, DNA, and other biomarkers have been developed and they are now routinely used as complementary diagnostic tools in clinical settings.

Antibody Detection

Complement fixation (CF), immunodiffusion (ID), and enzyme-immunoassay (EIA) are the most common techniques used to detect antibodies in the serum of patients with suspicion of fungal infection. Nowadays, these tests are mainly used for the diagnosis of endemic mycoses and chronic or allergic forms of aspergillosis. The sensitivity of these methods varies depending on the test (i.e., 59%–88% in chronic pulmonary aspergillosis; Page *et al.*, 2016) and/or the type of disease (i.e., 64%–97% for histoplasmosis; Falci *et al.*, 2017).

The main advantage of serological tests is the requirement of minimally invasive samples. Furthermore, results may be obtained when culture is negative and, if positive, the need of handling potentially infectious fungi is reduced (Kozel and Wickes, 2014). However, sensitivity is very limited in immunosuppressed patients due to the low antibody response and interpretation of serological results could be challenging since seropositivity remains long time after disease (Ramanan *et al.*, 2017; Richardson and Page, 2018).

Antigen Detection

The detection of fungal antigens in human body fluids has revolutionized the early diagnosis of invasive fungal infections. Several tests based on the detection of these antigens have been commercialized and included in the revised EORTC/MSG criteria for diagnosis of IFIs (Donnelly *et al.*, 2019). Table 1 summarizes main characteristics, sensitivity, and limitations of each technique.

Detection of 1,3- β -D-glucan (BDG) for diagnosis of fungal infection

BDG is a component of fungal wall, except in *Cryptococcus* spp. and Mucorales, which is released during infection. There are several commercial assays developed but only Fungitell (Associates of Cape Code, Inc., East Falmouth, MA, USA), a chromogenic quantitative enzyme immunoassay (EIA), has been approved by FDA (Theel and Doern, 2013). The detection of this antigen in serum has a great sensitivity in some important fungal infections as invasive candidiasis (IC), invasive aspergillosis (IA), and *Pneumocystis* Pneumonia (PCP) (Ambasta *et al.*, 2015; Cuenca-Estrella *et al.*, 2012; Karageorgopoulos *et al.*, 2011). However, there are many factors affecting the performance of the technique: (1) It cannot discriminate at species level, (2) causes a high rate of false positive results, (3) is presented in a closed commercial system, which commonly implies the shipment of sample to a reference laboratory, and (4) the efficiency of this test is reduced in solid organ transplant (SOT) patients (Cuenca-Estrella *et al.*, 2011; Lu *et al.*, 2011; Perfect, 2013).

Detection of galactomannan (GM) and glycoproteins for diagnosis of IA

The detection of GM, a polysaccharide present in the cell wall of most *Aspergillus* spp. which is secreted during infection, is commonly performed by using the commercial assay Platelia *Aspergillus* Ag EIA (Bio-Rad, Marnes-la-Coquette, FR). This technique has a great efficiency in serum of patients with hematological malignancies or hematopoietic stem cell transplant (HSCT) recipients, but sensitivity is drastically reduced in SOT patients, especially lung transplant recipients. In addition to serum, GM can also be efficiently detected in other samples such as bronchoalveolar lavage fluid (BALF), advancing IA diagnosis (Ambasta *et al.*, 2015; Steinbach, 2015). Despite these strengths, several limitations, such as cross-reactivity with other fungi and false positive (i.e., antibiotic treatment) or false negative results (i.e., antifungal treatment), deeply affect sensitivity and specificity of the technique (Lease and Alexander, 2011).

Last years, a new diagnostic technology has been developed based on immuno-chromatographic assays performed in lateral-flow devices (LFD). These “pregnancy tests-like” assays are cheap, sensitive, easy to use, and have low turnaround time (Prattes *et al.*, 2016). The *Aspergillus*-specific LFD test is based on the detection of an extracellular glycoprotein (different from GM) secreted by *Aspergillus* spp. constitutively during active growth (Thornton, 2008). This test can be performed in serum and BALF samples with comparable sensitivity to GM detection and higher specificity, although it shows cross-reaction with *Penicillium* spp. (Heldt and Hoenigl, 2017).

Table 1 Characteristics of the most used antigen detection methods for the diagnosis of fungal infections

Antigen	Organism	Sensitivity	Limitations
BDG	Panfungal (except <i>Cryptococcus</i> spp. and Mucorales)	IC > 65% (S) IA 50–80% (S) PCP 95%–96% (S)	No discrimination at species level False positives BDG absent in <i>Cryptococcus</i> spp. and Mucorales Closed commercial system Low efficiency in SOT patients (66%)
GM	<i>Aspergillus</i> spp.	71% (S) > 70% (BALF)	False positives (cross-reactivity with other fungi, antibiotics, etc.) False negatives (antifungal therapy) Low efficiency in SOT patients (22%)
LFDA <i>Aspergillus</i>	<i>Aspergillus</i> spp.	68% (S) 86% (BALF)	Cross-reactivity with <i>Penicillium</i> spp. Pre-treatment (S) Semi-quantitative test
CPA	<i>Cryptococcus</i> spp.	70% (S) 90% (CSF)	Cross-reactivity with other fungi Low efficiency in pulmonary forms (25%–56%)
CPA (LFDA) MNN/Anti-MNN Ig	<i>Cryptococcus</i> spp <i>Candida</i> spp.	≈ 100% (S/CSF) 83% (S)	Semi-quantitative test Low efficiency in non- <i>C. albicans</i> infections Not included in EORTC/MSG criteria
EFA	<i>H. capsulatum</i>	79% (S) 82% (U) 94% (BALF, MVista)	Cross-reactivity with other fungi Low efficiency in pulmonary forms in serum and urine samples Samples are required to be shipped to the company's facilities (MVista tests) Only tested in urine samples (IMMY test for <i>Histoplasma</i> antigen detection)
	<i>C. immitis</i> <i>B. dermatitidis</i>	84% (S/U) 93% (CSF) 57% (S) 90% (U)	

Source: BALF: Bronchoalveolar lavage fluid; BDG: 1,3- β -D-glucan; CPA: Capsular polysaccharide antigen; CSF: Cerebrospinal fluid; EFA: Endemic fungal antigens; GM: Galactomannan; IA: Invasive aspergillosis; IC: Invasive candidiasis; Ig: Immunoglobulin; MNN: Mannan; PCP: *Pneumocystis pneumonia*; S: Serum; SOT: Solid organ transplant; U: Urine.

Note: Reproduced from Original Work by Clara Valero.

Detection of capsular polysaccharide antigen (CPA) for the diagnosis of cryptococcosis

Latex-agglutination (LA) is the most used method for the detection of the CPA of *Cryptococcus* spp, particularly a component called glucuronoxylomannan (GXM), which is shed into blood and cerebrospinal fluid (CSF) during infection (Yauch *et al.*, 2005). This method can be performed in both serum and CSF being very useful for the diagnosis of cryptococcosis, especially in AIDS patients with cryptococcal meningitis, however the performance is reduced in patients with only pulmonary involvement (Baddley and Dismukes, 2011). An LFD is also available for the detection of CPA of *Cryptococcus* spp. with sensitivity even superior to the LA assay (Nalintya *et al.*, 2016).

Detection of mannan (MNN) for diagnosis of invasive candidiasis

The combined detection of MNN, a highly immunogenic component of *Candida* spp. cell wall that circulates in blood during infection, and anti-MNN Igs can be used for specific detection of *Candida* spp. in serum samples (Sendid *et al.*, 1999). EIAs quantifying MNN and anti-MNN Igs are commercialized as Platelia Candida Ag Plus and Platelia Candida Ab Plus (Bio-Rad, Marnes-la-Coquette, FR) and the combined detection shows acceptable sensitivity for the diagnosis of IC, although it is reduced in non-*albicans* *Candida* infections (Mikulska *et al.*, 2010).

Detection of endemic fungal antigens (EFA) for the diagnosis of endemic fungal infections

The detection of antigens produced by fungal species causing endemic mycoses such as *H. capsulatum*, *P. brasiliensis*, *C. immitis*, and *B. dermatitidis* represents a breakthrough in the diagnosis of endemic fungal infections.

The *H. capsulatum* polysaccharide antigen can be detected in both serum and urine samples with similar diagnostic value (Fandino-Devia *et al.*, 2016) and it can be performed by using two commercial assays: (1) *Histoplasma* Quantitative EIA Test (MiraVista Diagnostics, Indianapolis, IN, USA), and (2) the *Histoplasma* Antigen EIA kit (IMMY, Norman, OK, USA). MiraVista's test presents great efficiency in serum and urine samples from patients with disseminated infection, but it is reduced in patients with pulmonary forms of the disease (Hage *et al.*, 2015), in which BALF samples are more suitable for diagnosis (Hage *et al.*, 2011).

This test is only performed in MVista's facilities then is not accessible out of USA limiting their use. On the other hand, IMMY's test demonstrates a good agreement with MiraVista's but it has been only tested in urine samples (Falci *et al.*, 2017). Recently, a promising monoclonal *Histoplasma* galactomannan enzyme-linked immunosorbent assay has been developed by IMMY showing great performance and reproducibility (Cáceres *et al.*, 2018). MVista Diagnostics has also developed EIA tests for the diagnosis of coccidioidomycosis and blastomycosis. In the case of the detection of *Coccidioides* spp. antigen, it can be performed, in addition to serum and urine, in CSF samples. This means a great advantage in the diagnosis of coccidioidal meningitis, although sensitivity is lower in single respiratory infections (Kassis *et al.*, 2015). Finally, sensitivity for the detection of *B. dermatitidis* antigen varies deeply depending on the specimen employed, being more efficient in urine samples, however sample pre-treatment can enhance diagnostic performance (Smith and Gauthier, 2015). The main limitation of many of these assays is the high degree of cross-reaction with other fungi (Malcolm and Chin-Hong, 2013).

DNA-Based Methods/Molecular Methods

Methods based on the detection of DNA have been developed recently for the diagnosis of fungal infections. Their powerful advantages over conventional methods (simplicity, high specificity, and short turnaround time) have made them potential candidates to replace those traditional diagnostic assays (Arvanitis *et al.*, 2014).

PCR-based methods

The most relevant DNA detection methods are those that implement polymerase chain reaction (PCR). This technique is playing an increasingly role in the routine diagnostic of several laboratories of clinical microbiology as they offer a rapid, specific and sensitive detection of pathogens (Buchan and Ledebøer, 2014). Furthermore, quantitative or real-time PCR (qPCR) assays allow for determining the fungal DNA burden in patients by using non-specific DNA-binding dyes or fluorescently labeled probes (Kozel and Wickes, 2014). Despite of the advantages, most reported assays have been developed in house by different laboratories and just a reduced number of tests have been commercialized. Moreover, these techniques have several limitations: (1) The contamination risk of samples or the technique itself by environmental fungi, (2) the moderate amount of DNA in low invasive samples such as blood and serum, (3) the lack of standardization, and (4) the low availability of widely validated commercial systems (Alanio and Bretagne, 2017; Khot and Fredricks, 2009). Due to all these disadvantages, PCR has classically been excluded of the EORTC/MSG criteria for IFI diagnosis, however all efforts made last years have achieved its inclusion in the last update (Donnelly *et al.*, 2019).

Nowadays, there are two approaches for the diagnosis of fungal infections by using PCR:

- (1) Specific qPCR assays: The greatest efforts have been made in the detection of species causing important fungal infections such as IC, AI, and PCP (Fig. 3). However, there are considerably fewer qPCR studies for the detection of fungi causing neglected infections as histoplasmosis or emerging fungal infections as those caused by *Scedosporium* spp. or *Fusarium* spp. among others. Most developed methods target specific multicopy regions of the ribosomal DNA and are performed by using conventional or real-time PCR. One interesting approach based on specific qPCR assays is multiplex qPCR (MRT-qPCR), since it allows for detecting several pathogens in the same reaction tube. These assays are very useful for the differential diagnosis of fungal species with non-specific symptomatology (Gago *et al.*, 2014) or with different antifungal susceptibility profiles (Alonso *et al.*, 2012; Bernal-Martinez *et al.*, 2013; Foongladda *et al.*, 2014), and also allows for the detection of mixed infections. Recently, many efforts have been made in Europe, to try to achieve a consensus in the development of PCR diagnostic methods with the purpose of being included in the international guidelines (FPCRI; see "Relevant Websites section").
- (2) Panfungal or broad-range PCR assays (Fig. 3): These assays are very useful when there is not a clear suspicion of the fungus involved in the infection. Universal primers able to amplify any fungal species are used to detect fungal DNA in the clinical sample. Sensitivity values of these assays in paraffin-embedded biopsies range between 86%–94% in culture-proven cases and 64%–89% in cases confirmed by histopathology (Powers-Fletcher and Hanson, 2016). One of the main limitations of these techniques is the delay in response time due to the requirement of sequencing the amplified panfungal PCR product. Furthermore, specimen contamination and commensal fungi colonization of body sites of sampling could deeply affect the specificity of the technique (Khot and Fredricks, 2009). Some recent studies have developed other panfungal methods directed to reduce response time. One of these methods complements the use of panfungal primers with a melting curve analysis and probes able to detect genera or the group of fungi (Valero *et al.*, 2016). Others involve different identification techniques such as DNA microarray (Sakai *et al.*, 2014), electrospray-ionization MS analysis (Massire *et al.*, 2013), or T2 magnetic resonance (Pfaller *et al.*, 2016).

Non-PCR based methods

Alternative DNA-based methods for the diagnosis and identification on fungal infections are those based on in situ hybridization of labeled probes. The PNA-FISH (peptide nucleic acid-fluorescence in situ hybridization) method employs fluorescently labeled probes that bind complementary to fungal sequences and has been often used to identify *Candida* spp. from positive blood culture bottles. The probe color detected gives a preliminary indication of fluconazole susceptibility associated to the species (Klingspor *et al.*, 2018).

Fig. 3 Comparative scheme describing main characteristics, advantages, and limitations of both specific and panfungal PCR diagnostic techniques.

Similarly, chemiluminescent DNA probes are commercially available for the identification of endemic fungal species from positive cultures (Gomez, 2014) or tissues (Guarner and Brandt, 2011).

Future Directions and Conclusion

The aim of this chapter is to summarize those diagnostic methods commonly used for the diagnosis of fungal infections. As stated before, diagnosis of these infections is difficult and the combination of conventional and new techniques is essential for an early diagnosis. In addition, it is important to know the local epidemiology and prevalence of fungal infections as it can help choose the most appropriate diagnostic method that should be used (Lass-Flörl, 2017).

Nevertheless, fungal diagnostics is an area under continuous evolution since novel tests and new applications of already existing techniques are in constant development. In that context, the search for new biomarkers (both from the fungal pathogen and the human host) is a main objective for researchers. The detection of new fungal cell wall polysaccharides and second metabolites such as mycotoxins (Escriva et al., 2017) and volatile organic compounds (VOCs) (Acharige et al., 2018) have been reported in last years. Regarding already established techniques, the application of MALDI-ToF MS technology directly in clinical samples (Rizzato et al., 2015) have also gained great interest. In the case of the study of host factors, the increasing use of proteomic and bioinformatic approaches has promoted the research in this area with the aim of being able to predict susceptibility and risk of acquiring fungal infections as well as offering a personalized diagnosis (Lydon et al., 2018). Although many work should be done in this sense in coming years, several efforts have been already made in concern of some fungal infections such as IA (Oliveira-Coelho et al., 2015).

Alternatively, the development of “point of care” (POC) techniques have increased last years as an attempt to obtain robust and cheap methods to be used in less favored regions of the world. LFDs for the detection of *Cryptococcus* and *Aspergillus* are commercially available as previously mentioned, and one more for the diagnosis of histoplasmosis has just been released by MiraVista Diagnostics (Cáceres et al., 2019).

In summary, fungal infections are currently recognized as a cause of significant morbidity and mortality, especially among immunocompromised patients. Consequently, a proper and early diagnosis is essential to establish a suitable antifungal therapy that could allow for improving patient’s outcome. Although the ideal diagnostic method or strategy is still missing, several efforts have been made in last years, which have led to a new generation of diagnostic tools. Undoubtedly, so much remains to be done in this context, from widely standardizing and validating already developed tests through large multicenter studies to exploring

combination testing or adapting antigen and DNA detection methods to POC platforms. All this efforts will end in the construction of a proper panel of fungal diagnostic methods that could be available wherever it is required.

Commensal to Pathogen Transition of *Candida albicans*

Ilse D Jacobsen, Maria J Niemiec, Mario Kapitan, and Melanie Polke, Hans Knöll Institute, Jena, Germany

© 2021 Elsevier Inc. All rights reserved.

Glossary

Attenuated (virulence) Reduced capacity to induce damage/disease.

Biofilm A structured community of microorganisms that adhere to each other and are commonly embedded within a self-produced extracellular matrix composed of polysaccharides, proteins, and DNA.

Candidiasis Infections caused by *Candida* species.

Colonization Growth (or prolonged survival) of microorganisms in a distinct (host) niche.

Commensal Microorganism that grows within a host without (negatively) affecting the host species.

Dysbiosis Disturbance of the microbiota leading to microbial imbalance and commonly reduced species diversity; often associated with increased abundance of a few taxa or species.

Filamentation The production of filamentous growth forms (hypha, pseudohypha).

Hypha Long, filamentous fungal cells, characterized by directed growth at the tip, branching, parallel cell walls, and the absence of constriction at the septa separating individual cells.

Hypha-associated Genes or proteins that are usually only expressed by hypha and not by yeast cells.

Inoculation Introduction of a microorganism into a host or growth medium.

Macronutrients Nutrients that provide energy, for example, carbohydrates and amino acids.

Microbiota Ecological community of commensal, symbiotic, and pathogenic microorganisms found at a distinct site/within a distinct host niche.

Micronutrients Nutrients required by organisms throughout life in small quantities as necessary cofactors for metabolism, for example, trace minerals and vitamins.

Morphogenesis The process by which an organism develops its shape. In the context of *Candida* it usually refers to the formation of hypha from yeast cells, whereas the term “reverse morphogenesis” is sometimes used to describe the formation of yeast cells from filamentous growth forms.

Morphotype Morphological growth form; *C. albicans* has different morphotypes, e.g., yeast, pseudohypha, and hypha.

Mycobiota Ecological community of fungi found at a distinct site/within a distinct host niche.

Nosocomial infection An infection contracted by a patient while under medical care.

Opportunistic infection An infection that usually does not occur in healthy hosts but only if predisposing factors (weakened immune system, breached epithelial barriers) are present that give the pathogen the opportunity to establish an infection.

Pathobiont A microorganism that under normal circumstances lives as a commensal but has the potential to cause disease.

Pathogen A microorganism that causes disease.

Pathogenesis The mechanisms leading to disease.

Pseudohypha Elongated fungal cells, characterized by constrictions between individual cells.

Pyroptosis A form of programmed cell death of immune cells that occurs most frequently upon infection with intracellular pathogens and leads to the release of pro-inflammatory cytokines, thereby contributing to inflammation.

Virulence The ability of microorganisms to cause damage to a host.

Virulence factor Gene or attribute that contributes to the virulence of a pathogen.

Introduction: *Candida albicans* as Commensal and Pathogen

Candida albicans is an archetypical opportunistic pathogen: While it is the most common cause of systemic fungal infections, it is also carried by two out of three humans on mucosal membranes without causing any damage (Richardson and Rautemaa, 2009; Thewes and Hube, 2008; Kett *et al.*, 2011; Odds, 1987; Pfaller and Diekema, 2007). As a commensal, the fungus is commonly found within the oral cavity, gastrointestinal tract (GI tract), and on the urogenital mucosa. On all sites, it has to adapt to the local environment that differs significantly between various anatomical locations. Environmental conditions are on the one hand defined by properties of the local mucosa. On the other hand, *C. albicans* has to establish its niche within the complex microbiota that also varies depending on the anatomical site (Morgan *et al.*, 2013). Adaptation to these different niches requires versatile nutrient acquisition, metabolic flexibility, and stress resistance.

C. albicans' adaptability contributes to its success as an opportunistic pathogen. If the balance between host defense systems, microbiota, and *C. albicans* is disturbed, for example, due to immunosuppression, impairment of mucosal barrier integrity, or disturbance of the bacterial microbiota by antibiotics, *C. albicans* can cause both local and disseminated infections (Goncalves *et al.*, 2016; Kullberg and Arendrup, 2015; Suleyman and Alangaden, 2016). Mucosal infections can occur at all sites that are colonized with *C. albicans* and are often associated with specific risk factors that do not predispose to infections at other sites: For example, oropharyngeal candidiasis is very common in AIDS patients but these patients do not have an increased risk for other

forms of candidiasis (Fidel, 2011). Chronic mucocutaneous candidiasis is often associated with mutations that impair Th17 immunity; although continuously suffering from invasive local candidiasis, whether these patients also have an increased risk for disseminated infection depends on the exact kind of mutation in the IL17 signaling pathway (Okada *et al.*, 2016). These examples illustrate the complexity and niche-specificity that applies to the host-pathogen interactions that control the commensal-to-pathogen shift in *C. albicans*.

In the following parts, we will summarize the current knowledge on which features make *C. albicans* a successful commensal focusing on the GI tract, and discussing some of the main attributes that contribute to its success as an opportunistic pathogen.

***Candida albicans* as a Commensal: Living with the Host and Microbial Neighbors**

As mentioned above, both the environmental conditions and the present microbiota vary between different mucosal sites. Consequently, different aspects of *C. albicans* physiology contribute to varying extend to fungal survival in the different mucosal niches. In the following part, we focus on the GI tract; for further information on *C. albicans* as a commensal and pathogen in the oral and vaginal niche we refer the reader to recent comprehensive reviews (Cassone, 2015; Donders and Sobel, 2017; Goncalves *et al.*, 2016; Hebecker *et al.*, 2014; Lalla *et al.*, 2013; Peters *et al.*, 2014; Singh *et al.*, 2014; Bradford and Ravel, 2017; Yano *et al.*, 2018; Swidergall and Filler, 2017).

Fungal Factors That Contribute to *C. albicans* Survival in the Human Gut

In the human body, the GI tract is not only the major reservoir of *C. albicans*, but also the dominant source for candidiasis, a life-threatening systemic infection caused by this yeast (Mittal and Coopersmith, 2014). Research in fact provides evidence that the majority of systemic *Candida* infections are endogenous, so patients are infected with their very own *C. albicans* strains (Miranda *et al.*, 2009). As fungi were long underrepresented in microbiome studies due to technical reasons, the exact densities of fungi in the GI tract and other body niches are still poorly understood. However, there is increasing interest toward the entity of fungi living on and in the human body, termed mycobiota, and its interaction with the human host (Underhill and Iliev, 2014). In approximation, recent studies estimate at least 0.1% of all microorganisms (so 10^{11} out of 10^{14}) in the human GI tract to be fungi (Qin *et al.*, 2010; Ianiro *et al.*, 2016). In this context, it is interesting that *C. albicans* is among the few microbial species enriched in the patients upon intensive care, while the overall microbial diversity under these circumstances is decreased (Zaborin *et al.*, 2014). *Candida* colonization is also more common among patient with GI tract pathologies, like inflammatory bowel disease (IBD) or Crohn's disease (Kumamoto, 2011; Iliev *et al.*, 2012), and might contribute to pathogenesis by promoting inflammation following fungal overgrowth (Kumamoto, 2011). However, recent studies demonstrated also beneficial effects of fungal colonization, including but not limited to *C. albicans*, on the immune system and immunological disorders such as asthma (Jiang *et al.*, 2017; Wheeler *et al.*, 2016) and reviewed in Kumamoto (2016). Thus, even though the role of fungi as colonizers in the gut is not yet fully understood, it appears likely that fungi are important players in the intestinal microbiota, with the consequences of fungal colonization depending on underlying diseases or dysbiosis.

Antibiotic treatment reducing the number of bacteria is associated with increased fungal colonization (Underhill and Iliev, 2014). This indicates that *C. albicans* is well adapted to the GI tract and can grow to high densities if bacterial competition is reduced. This is supported by a recent study in germ free mice, in which a single inoculation results in stable, high level intestinal colonization (Böhm *et al.*, 2017). While colonization alone does not lead to infection (Koh *et al.*, 2008; Böhm *et al.*, 2017), increased colonization with *C. albicans* constitutes a risk factor for candidiasis (Muskett *et al.*, 2011). Thus, recent research increasingly focuses on the properties that allow the fungus to colonize mucosal surfaces and especially the gut (reviewed in Prieto *et al.*, 2016; Perez, 2019).

Within the length of the GI tract, and across the diameter of the intestine, several environmental parameters, including pH, oxygen and nutrient availability, and concentrations of hydrolytic enzymes and antimicrobial peptides, vary significantly (Zheng *et al.*, 2015a; Khutoryanskiy, 2015). Some of these factors are interconnected: The pH for instance ranges from highly acidic in the stomach to alkaline in the small intestine. It influences availability of micronutrients, such as iron, the proton gradient, that is important for nutrient uptake, and affects the efficacy of fungal enzymes (Davis, 2009). *C. albicans* can grow within a broad pH range, mediated by the sensing of environmental pH via the plasma membrane receptors Rim21 and Dfg16. The associated signaling cascade leads to activation of the transcription factor Rim101 at neutral to alkaline pH. Other factors involved in the response to changing pH are the cell wall β -glycosidases Phr1 and Phr2, Mds3, and calcineurin. Additionally, *C. albicans* is able to actively increase the local pH by metabolizing amino acids or polyamines, leading to the production and release of ammonia (Vylkova *et al.*, 2011). Interestingly, the pH affects the exposure of β -glucan, an important Pathogen-associated Molecular Pattern, on the cells surface of *C. albicans* and thereby influences fungal recognition by immune cells (Sherrington *et al.*, 2017). Similarly, β -glucan exposure is reduced at hypoxia (Pradhan *et al.*, 2018; Lopes *et al.*, 2018). Reduced exposure of β -glucan supports competitive fitness of *C. albicans* during intestinal colonization (Sem *et al.*, 2016), suggesting that environmental cues affecting cell wall architecture regulate commensal behavior of the fungus. In addition, it was recently shown that production of inflammatory mediators by the fungus contributes to intestinal fitness in the presences of phagocytes (Tan *et al.*, 2019). Together, this suggests an active role of the host immune system in shaping the mycobiota, even in the absence of inflammation. Furthermore, *C. albicans*

colonization affects not only the mucosal but also systemic immune responses, especially the response of innate immune cells to invading pathogens (Tso *et al.*, 2018; Shao *et al.*, 2019).

Although the gastrointestinal tract might appear rich in nutrients, specific types of carbon and nitrogen sources can be scarce in distinct microniches (recently reviewed in Fischbach and Sonnenburg, 2011; Flint *et al.*, 2012). Furthermore, *C. albicans* has to compete with other members of the microbiota for available nutrients. The metabolism of *C. albicans* is very versatile and the fungus can use a wide range of both carbon and nitrogen sources (Brown *et al.*, 2014; Ene *et al.*, 2014). Peptides, amino acids, sugars, and organic acids can be taken up by specific transporters and used to produce energy or as building blocks. As they commonly need to be released or extracted from macromolecules, *C. albicans* possesses a number of proteases and lipases to support nutrient liberation (Polke *et al.*, 2015). Typically, those enzymes include secreted aspartic proteases (Saps), lipases (Lips), and Plb phospholipases as well as several enzymes for the degradation of polysaccharides (Klis and Brul, 2015).

Overall, the gene expression of *C. albicans* colonizing the mouse gut appears to be distinct from other profiles. By comparing *C. albicans* cells invading host tissue during disease with *C. albicans* colonizing the mouse cecum, interesting similarities were revealed, but also niche- and mode-specific differences were detected (Thewes *et al.*, 2007; Walker *et al.*, 2009; Zakikhany *et al.*, 2007; Rosenbach *et al.*, 2010). The commensal gene expression profiles shared similarities with both, logarithmically growing cells and cells in stationary phase under standard in vitro conditions (Rosenbach *et al.*, 2010). The glucose metabolism was induced even though the gut is considered to be a low-glucose niche (Rosenbach *et al.*, 2010). Remarkably, although *C. albicans* grows predominantly as yeast in the mouse cecum (see also below), several genes that encode certain adhesins, were also expressed despite that they were previously thought to be hypha-associated (Herwald and Kumamoto, 2014; Rosenbach *et al.*, 2010).

So far, studies aiming at experimentally testing the contribution of factors to *C. albicans* fitness as a commensal of the gastrointestinal tract have focused mainly on transcription factors (TFs) due to their central role for controlling expression of physiological traits. One well studied TF is Efg1 that is involved in filament formation (Stoldt *et al.*, 1997). *EFG1*-deficient *C. albicans* strains are unable to form filaments under many in vitro conditions (Stoldt *et al.*, 1997). In colonization experiments using mice, Efg1 influences *C. albicans* survival in the GI tract as *EFG1*-deficient strains were found to be more efficient colonizers of the mouse gut (Pierce *et al.*, 2013). The stress response in the cecum was also induced in an Efg1-dependent manner (Pierce *et al.*, 2013). Further TFs required for *C. albicans* filamentation under certain laboratory conditions and important for GI tract colonization are Cph2 and Tec1 (Rosenbach *et al.*, 2010). Another transcription factor involved in the intestinal commensal state is Efh1, a paralog of *EFG1* whose deletion does not affect filamentation under in vitro conditions (Doedt *et al.*, 2004). Efh1 appears to actively promote *C. albicans* commensalism but is dispensable for systemic infections (White *et al.*, 2007). Using a signature-tagged mutagenesis approach, Pérez *et al.* tested a library of 77 TFs that did not affect growth in vitro to assess their ability to colonize the mouse gut. Thereby they identified six factors that contributed to colonization in antibiotic-treated mice: *TYE7*, *RTG1*, *RTG3*, *LYS144*, *HMS1*, and *orf19.3625* (Pérez *et al.*, 2013). *Rtg1*, *Rtg3*, *Tye7*, and *Lys144* affect expression of genes involved in nutrient acquisition and metabolism (Pérez and Johnson, 2013; Rosenbach *et al.*, 2010). *ZCF8*, *ZFU2* and *TRY4* were recently identified as additional factors in a similar screening conducted in germ free mice (Böhm *et al.*, 2017). An alternative approach, using overexpression strains, identified *CRZ2*, a TF affecting both expression of cell wall-modifying enzymes and promoting resistance to acidic pH and bile salts (Znaidi *et al.*, 2018). Furthermore, *C. albicans* mutants lacking the gene *PHO4*, encoding a transcription factor involved in phosphate metabolism, were outcompeted by the wild type during colonization (Urrialde *et al.*, 2016). These results thus underline the role of metabolic adaptation and nutrient acquisition for fitness in the gut. Finally, the kinase *Hog1*, a central factor in the general stress response of *C. albicans*, was shown to contribute to intestinal fitness (Prieto *et al.*, 2014), indicating that *C. albicans* is exposed to stressful conditions in this environment.

The current knowledge implies that morphogenesis, metabolism, and stress response affect *C. albicans* survival in the gastrointestinal tract (Pérez, 2019). This picture is certainly still incomplete and ongoing research will likely provide further information on distinct factors influencing the life of *C. albicans* as a gut commensal in the near future.

Morphology of *C. albicans* in the Gut

One of the most remarkable features of *C. albicans* is its morphological flexibility (Noble *et al.*, 2016). This includes growth as typical round, budding yeasts and filamentous growth either as long true hyphae or pseudohyphae. Both morphotypes are essential for virulence: Yeasts are highly proliferative and thought to be important for dissemination, while hyphae are important for invasion and tissue destruction (Gow *et al.*, 2002; Whiteway and Oberholzer, 2004; Jacobsen *et al.*, 2012). While yeasts, pseudohyphae, and hyphae are isolated from sites of infection, filamentous forms of *C. albicans* are found only rarely during gut colonization (Noble *et al.*, 2016; Kayser, 2010; White *et al.*, 2007). As the intestinal environment provides strong triggers for filamentation (e.g. 37°C, high CO₂, and peptidoglycan shed by bacteria) (Sudbery, 2011; Noble *et al.*, 2016; Wang and Xu, 2008), the absence of prominent filamentation is unlikely due to a lack of hypha induction but more likely mediated by other environmental factors. Furthermore, increasing evidence indicates that growth in the yeast form is favoring intestinal colonization (Böhm *et al.*, 2017).

In addition to normal yeasts, also known as white α/α cells, a gut-specific yeast-like morphotype termed GUT (gastro-intestinally-induced transition) was recently identified in this particular niche (Pande *et al.*, 2013). GUT cells are phenotypically and metabolically distinct from other morphotypes and can be produced by passaging *C. albicans* through the murine gastrointestinal tract. GUT cells are characterized by overexpressing *WOR1*, encoding a transcription factor that is not expressed in white

cells and controls the white-opaque switching important for mating (Huang *et al.*, 2006). However, GUT cells are distinct from mating-competent opaque cells and remain heterozygous at the mating type locus. Compared to other yeast forms, GUT cells have an elongated shape with smooth surface leading to altered colony morphology. GUT cells outcompete white cells in murine colonization, possibly due to an adapted metabolism that facilitates highly efficient utilization of the nutrients available in the gut (Pande *et al.*, 2013).

Animal Models Used to Investigate *C. albicans* Commensalism in the Gut

Currently, our knowledge on specific factors required for commensalism in the gut is still limited and nearly exclusively deduced from studies in mice, and a few studies in rats (Koh, 2013). Still, there are significant differences between humans and mice that need to be kept in mind when transferring knowledge from one organism to the other. Differences that might influence pathogenesis of infections are, for example, the composition of blood leukocytes, the functionality of neutrophils, or the inflammatory response (Mestas and Hughes, 2004; Seok *et al.*, 2013; Ermet *et al.*, 2013; Warren, 2009). At the commensal state of *Candida*, there are also some factors to be considered when mimicking men in mice. Laboratory mice are usually not colonized with *C. albicans*, even though other *Candida* species such as *C. krusei* can be present (Dollive *et al.*, 2013). This might point to a distinct role of the murine gut microbiota mediating colonization resistance toward *C. albicans*. However, differences in exposure might affect these findings. Laboratory mice kept under hygienic conditions are probably more likely to harbor environmentally-derived yeasts (such as *C. krusei*) than *C. albicans* that is only found associated with warm-blooded hosts (Odds, 1987). Furthermore, timing of exposure might be relevant. Humans are believed to be colonized during birth or the first days of life when the gut microbiota is in its earliest stages. Indeed, also infant mice are more susceptible both to colonization and spontaneous dissemination of *C. albicans* (Guentzel and Herrera, 1982; Pope *et al.*, 1979). Furthermore, food composition affects colonization resistance (Kadosh *et al.*, 2016; Gunsalus *et al.*, 2016).

In general, however, many studies have shown that the gut microbiota of adult mice and other rodents mediates colonization resistance toward *C. albicans* (Kennedy and Volz, 1985a,b; Koh, 2013; Fan *et al.*, 2015). Therefore, depletion of bacteria is necessary to facilitate stable colonization of adult mice with *C. albicans* (see Fig. 1). Experimental procedures published in different studies vary in the choice of antibiotics and *C. albicans* inoculation regiment (selected recent examples in Table 1), but mutually a combination of antibiotics is used. The infectious dose appears to have less influence on long-term colonization as proliferation to high, stable colonization levels occurs within a few days, even after inoculation of a minimal dose of 100 *Candida* cells (Prieto and Pla, 2015). Importantly, colonization experiments with single *C. albicans* mutants might not always reveal the influence of genes on colonization efficiency and competition experiments might be required to detect fitness defects (Prieto *et al.*, 2014).

According to our current understanding, *C. albicans* generally does not spontaneously disseminate in significant numbers from the gut to the blood stream of adult mice (Ekenna and Sherertz, 1987; Koh, 2013). In order to achieve translocation and disseminated infection, impairment of the epithelial barrier and suppression of the innate immune system is required (Koh *et al.*, 2008). This can be achieved, e.g., by induction of colitis using the detergent dextran sulfate sodium and selective depletion of neutrophils. Alternatively, treatment with cyclophosphamide, a chemotherapeutic drug leading to the death of fast-proliferating cells, results in a combination of both, reduced barrier function of the enteric epithelium and immunosuppression via leukopenia (see Fig. 1). Consequently, mice treated with cyclophosphamide are more likely to develop disseminating candidiasis originating from the gut (Ekenna and Sherertz, 1987). Murine sepsis models based on mechanical disruption of the gut, such as cecal ligation and puncture, are not

Experimental set-up for *C. albicans* colonization and dissemination from the mouse gut

Fig. 1 Set-up for *C. albicans* colonization and dissemination from the mouse gut. Widely-used experimental strategies to reduce the pre-existing microbiota (blue), to colonize with *C. albicans* (C.a., green) and to induce dissemination (orange) from the mouse gut. Illustration by I.D. Jacobsen.

Table 1 Overview of colonization strategies with antibiosis prior to *Candida albicans* inoculation of mice

Antibiosis	Inoculum	<i>C. a.</i> strain	CFUs/g feces	Time point p.i.	References
Bacitracin Streptomycin Gentamycin	Oral gavage, 10 ⁷ cells	CAF2	10 ⁶ –10 ⁷	3 d	(Wiesner <i>et al.</i> , 2001)
Tetracycline Streptomycin Gentamycin	Oral gavage, 5 × 10 ⁷ cells	DAY185	10 ⁵	18 d	(White <i>et al.</i> , 2007)
Streptomycin Penicillin G	Drinking water, 10 ⁷ CFUs/mL	SC5314, CAF2–1	10 ⁷	21 d	(Koh <i>et al.</i> , 2008)
Tetracycline Streptomycin Gentamycin	Oral gavage, 5 × 10 ⁷ cells	CKY101	10 ⁷	3 d	(Pierce <i>et al.</i> , 2013)
Streptomycin Bacitracin Gentamycin	Oral gavage, 10 ⁷ cells	CAF2	10 ⁶ –10 ⁷	40 d	(Prieto <i>et al.</i> , 2014)
Streptomycin Bacitracin Gentamycin	Oral gavage, 10 ⁶ cells	CAF2	10 ⁷	3 d	(Prieto and Pla, 2015)
Streptomycin Penicillin	Drinking water, 10 ⁷ CFUs/mL	SC5314	10 ⁶ –10 ⁷	10 d	(Vautier <i>et al.</i> , 2015)

Note: Colonization strategies presented in different publication varied in choice of antibiotics, application procedure, dosage of *C. albicans* (*C.a.*) inoculum, and stability of colonization (by fungal load in feces) as finally the time point of analysis.

commonly used as a model for gut-derived candidiasis (Toscano *et al.*, 2011; Warren, 2009), but might be an alternative approach. A typical experimental set-up for a colonization-dissemination experiment as currently used in the field is depicted in Fig. 1.

Candida albicans as Part of the Microbiota

In addition to immunosuppression and breach of mucosal barriers, the disturbance of the microbiota constitutes a major risk factor for disseminated candidiasis. Long-term antibiotic treatment and malnutrition during intensive medical care are prominent causes of dysbiosis (Zaborin *et al.*, 2014). This indicates that the *C. albicans* population in the gut is usually controlled by commensal bacteria and possibly other fungi colonizing the respective niche in the body. This is mirrored in mouse models of *Candida* gut colonization: As mentioned above, extensive antibiosis prior to introduction of the fungus is necessary to achieve stable colonization with *C. albicans* (Koh, 2013; Fan *et al.*, 2015). Like the bacterial microbiota, the fungal “mycobiota” is more and more appreciated for its immune-modulatory properties, and not only as a source of infection (Gouba and Drancourt, 2015; Suhr and Hallen-Adams, 2015; Underhill and Iliev, 2014). To date, little is known about the exact mechanisms of microbial competition and microbe-microbe interaction and microbe-host cross-talk and how this affects host health and disease development. Yet, recent research provides evidence for an intricate interplay of many actors that exceeds simple competition for resources.

Notably, interactions between microbes are numerous and occur naturally on all surfaces of the human body, i.e., the skin, the lung, the oral cavity, the urogenital tract and the gastro-intestinal tract (Peters *et al.*, 2012; Peleg *et al.*, 2010). The specific nature of these interactions varies depending on the species involved, but it can be expected that some general concepts are conserved. To date only few studies have specifically addressed the interactions of *C. albicans* with intestinal bacteria. Here, we will briefly summarize the current knowledge on *Candida*-bacteria interplay in general (for more detailed information we refer to Polke *et al.* (2015), Allison *et al.* (2016) and Förster *et al.* (2016)).

Candida and bacteria can interact by (1) direct physical contact, (2) communication via released molecules, and (3) indirectly by modification of the environment and the host response. Given the high density of microorganisms on mucosal surfaces, direct contact is highly anticipated. Interestingly, different bacteria have been described form aggregates with *C. albicans* and are often found to bind fungal hyphae better than yeast cells (Peters *et al.*, 2010; Harriott and Noverr, 2010; Schlecht *et al.*, 2015; Brand *et al.*, 2008; Bamford *et al.*, 2009; Adam *et al.*, 2002; Kong *et al.*, 2015; Bagg and Silverwood, 1986; Harriott and Noverr, 2011; Holmes *et al.*, 1996; Jenkinson *et al.*, 1990; Metwalli *et al.*, 2013; Shirliff *et al.*, 2009). Binding can involve both *C. albicans* and bacterial adhesins as well as mannosylation of fungal surface proteins (Schlecht *et al.*, 2015; Kong *et al.*, 2015; Tati *et al.*, 2016; Bamford *et al.*, 2009; Brady *et al.*, 2010; El-Sabaeny *et al.*, 2000; Holmes *et al.*, 1996; Klotz *et al.*, 2007; Silverman *et al.*, 2010; Wright *et al.*, 2013; Dutton *et al.*, 2014). In the oral cavity, these interactions can promote *C. albicans* colonization and persistence (Cannon and Chaffin, 2001; Shirliff *et al.*, 2009). Furthermore, adhesion to invading *C. albicans* hyphae can aid bacteria that otherwise would be unable or little efficient to penetrate host cells, as it has been shown for *Staphylococcus aureus* (Kong *et al.*, 2015; Schlecht *et al.*, 2015; Alves *et al.*, 2014). Synergistic interactions of *C. albicans* and

bacteria are also found in mixed species biofilms, an important source of nosocomial infections (Shirliff *et al.*, 2009; Hirota *et al.*, 2017; Taff *et al.*, 2013). Bacteria, including species present in the gut such as *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, *Enterococcus faecalis*, or *Salmonella typhimurium*, have been found to also affect filamentation of *C. albicans*, an effect often mediated by small, secreted signaling molecules (Hogan *et al.*, 2004; Brand *et al.*, 2008; Peleg *et al.*, 2008; Kim and Mylonakis, 2011; Cruz *et al.*, 2013; van Leeuwen *et al.*, 2016; Graham *et al.*, 2017). Most of these interactions negatively affect hypha formation and it is thus tempting to speculate that it is the microbiota that keeps *C. albicans* in the less invasive yeast form in the gut (Förster *et al.*, 2016). Reducing bacterial microbiota by antibiotics might relieve this restriction and thereby promote filamentation and invasion; however, yeasts are the dominant morphotypes of *C. albicans* also in the gut of mono-colonized germ free mice, indicated that interactions with bacteria are not necessary to promote this morphology in the intestine (Böhm *et al.*, 2017).

Recent studies indicate that the human gut microbiota is very diverse with more than 1000 bacterial species and up to 75 fungal genera described (Qin *et al.*, 2010; Mar Rodriguez *et al.*, 2015). It furthermore becomes increasingly clear that a balanced composition of bacteria and fungi is correlated to intestinal health, while dysbiosis is accompanied with a range of diseases (Wheeler *et al.*, 2016; Sokol *et al.*, 2016; Mittal and Coopersmith, 2014; Lagunes and Rello, 2016). The composition of the microbiota affects *C. albicans* survival in the gut and non-pathogenic gut-residing bacteria, i.e., Firmicutes and Bacteroidetes, are involved in maintaining *C. albicans* colonization resistance in mice (Fan *et al.*, 2015). One specific member of this group, *Bacteroides thetaiotaomicron*, was demonstrated to mediate this effect by inducing the production of host antimicrobial effectors (Fan *et al.*, 2015). Another group of bacteria with antagonistic relations to *C. albicans* are lactobacilli. Lactobacilli negatively affect *C. albicans* colonization both by direct mechanisms, modification of the environment, and indirectly via cross-talk with host cells (Wynne *et al.*, 2004; Romani *et al.*, 2015; Kelly *et al.*, 2015; Noverr and Huffnagle, 2004; Graf *et al.*, 2019). While not being the only source, lactobacilli are known for their capacity to produce short-chain fatty acids (SCFAs) in the gut. SCFAs were demonstrated to increase barrier function of the gut epithelium and inhibit *C. albicans* filamentation (Kelly *et al.*, 2015; Noverr and Huffnagle, 2004) and this mechanism might also contribute to colonization resistance and yeast growth.

Notably, while *C. albicans* is clearly affected by bacteria in the gut, the fungus likewise affects composition of the bacterial community and bacterial virulence. In mice, the introduction of *C. albicans* affects the composition and development of the intestinal microbiota after antibiotic depletion, leading to an enrichment of *Bacteroidetes* and *E. faecalis*, but slower regrowth of lactobacilli (Erb Downward *et al.*, 2013). The fungus is also associated with expansion of enterococci in the oral cavity (Bertolini *et al.*, 2019). *C. albicans* furthermore dampens the virulence of *P. aeruginosa* in a colonization-dissemination model by reducing the expression of bacterial virulence factors (Lopez-Medina *et al.*, 2015). In contrast, by modification of environmental pH, *C. albicans* leads to increased expression of *Staphylococcus aureus* virulence factors (Todd *et al.*, 2019a,b). In addition, *C. albicans* was also shown to promote growth of obligate anaerobic *Clostridium* spp. under aerobic conditions, potentially boosting their ability to colonize the human gut (van Leeuwen *et al.*, 2016; Fox *et al.*, 2014). However, the effects of *C. albicans* colonization on *Clostridium difficile* infection of the gut are contradictory (Markey *et al.*, 2018; Panpetch *et al.*, 2019). While we are just at the beginning of unraveling the triangle of *C. albicans*, gut-residing bacteria and the human host, these findings indicate that bacterial-fungal interactions affect not only the composition of the microbiota but might also significantly influence the development of either bacterial or fungal infections.

Features That Contribute to the Success of *C. albicans* as Pathogen

Virulence is a multi-faceted feature of microorganisms that includes the ability to thrive within host tissue, withstand rapid elimination by the immune system and the capability to cause tissue and/or organ damage. Keeping this in mind, it is not surprising that genes involved in various processes, from basic cell biology to specific interactions with host cells, have been demonstrated to affect the virulence potential of *C. albicans* (see da Silva Dantas *et al.* (2016) for an overview). Here, we will focus on factors that influence the interaction of the fungus with host cells, nutrient acquisition and will briefly discuss the role of the cell wall and morphogenesis for candidiasis.

Interaction of *Candida albicans* with Epithelial Cells

As a commensal *C. albicans* lives in close contact with – or depending on the presence of a mucus layer, in proximity to – epithelial cells without causing overt damage. This changes during infection characterized by increased fungal load, invasion into epithelial barriers (and underlying tissue), induction of an immune response and tissue damage. The factors that trigger the transition from commensalism to infection are only incompletely understood, but the disturbance of the microbiota clearly plays an important role (Fan *et al.*, 2015; Lopez-Medina *et al.*, 2015) and recently reviewed in Förster *et al.* (2016) and Höfs *et al.* (2016).

The first step toward infection is attachment of the yeasts to host cells, in the case of mucosal membranes epithelial cells (Fig. 2). This complex process is likely initiated by passive forces, e.g., hydrophobic cell-cell interactions, followed by specific interactions between fungal and host cell surface molecules (a comprehensive overview has been published by Moyes *et al.* (2015)). While some adhesins also occur on yeast cells, hyphae express adhesins, like Als3 and Hwp1, in larger number and more efficiently (Wächter *et al.*, 2011; Phan *et al.*, 2007). Targeted host structures include cadherins, integrins, and components of the

Fig. 2 Adhesion, invasion, and damage by *C. albicans* in the human gut. Major steps of the *C. albicans* life-cycle during the switch from commensal to pathogen. Hyphae-associated adhesins (blue anchors) mediate the attachment to enterocytes. Growing hyphae and subsequent release of candidalysin and proteases (orange scissors) and lipases penetrates enterocyte barrier and destroys underlying cell layers. Illustration by M.J. Niemiec and M. Polke.

extracellular matrix (Phan *et al.*, 2007; Zhu *et al.*, 2012; Chaffin, 2008). Of note, adhesion to host cells is a strong trigger for filamentation in vitro and hypha formation is important for the second step during infection: invasion (Fig. 2). Invasion into host cells occurs by two mechanisms, induced endocytosis and active penetration. Active penetration is a fungal-driven process that requires directed filamentous growth (Wächter *et al.*, 2012). The current knowledge suggests that in addition to physical forces provided by the turgor pressure, hydrolytic enzymes, especially secreted aspartic proteases (Saps) support this process. Inhibition of aspartic proteases by pepstatin A significantly reduces invasion (Dalle *et al.*, 2010); the contribution of individual Saps to this process is however still controversially discussed (Naglik *et al.*, 2003, 2008). In contrast to active penetration, induced endocytosis requires the activity of host cells and occurs even with inactivated fungal cells. It is initiated by the recognition of distinct fungal surface proteins (“invasins”) by host cell receptors, which triggers rearrangement of the cytoskeleton leading to uptake of the fungal cell. The first *C. albicans* invasin identified was Als3 that binds to cadherins on host cells (Phan *et al.*, 2007). Another known *C. albicans* invasin is Ssa1 and further host receptors include the EGF receptor and the human epidermal growth factor receptor 2 (Zhu *et al.*, 2012; Sun *et al.*, 2010). Importantly, as Als3 is a hypha-specific protein, both active penetration and induced endocytosis depend largely on hypha formation. Therefore, hyphae are considered to be the invasive morphology in *C. albicans*.

Invasion is a prerequisite for damage but not necessarily linked to damage of host cells: As the host membrane remains intact following initial invasion, forming a glove-like structure surrounding growing hyphae (Wächter *et al.*, 2012; Zakikhany *et al.*, 2007), the host cell is not immediately lysed. Indeed, specific *C. albicans* mutants have been identified that show unaltered adhesion and invasion but significantly reduced damage in the interaction with epithelial cells. One of these mutants is *C. albicans* *eed1Δ/Δ*, lacking *EED1*, a factor that is essential for maintenance of hyphal growth and thus hyphal elongation. Following invasion, this mutant reverts back to yeast growth intracellularly, thereby reducing the strain on the host cell membrane afflicted by growing hyphae of wild type *C. albicans* (Zakikhany *et al.*, 2007; Martin *et al.*, 2011). Other examples are mutants lacking either *DUR31* or *HSP21*, that likewise show reduced hyphae formation following invasion (Mayer *et al.*, 2012a,b). Most important, however, was the discovery that an *ECE1* deletion mutant is highly attenuated in epithelial damage, despite normal filamentation. *ECE1* was already identified in the 1990s as one of the genes most highly expressed on hyphae compared to yeast cells (Birse *et al.*, 1993). Yet again, its function was only elucidated in 2016 (Moyes *et al.*, 2016): *ECE1* codes a protein that is cleaved into eight short peptides by Kex2. Peptide 3 generated by this cleavage adopts an α -helical structure and integrates into host cell membranes, leading to permeabilization and lysis. Due to this effect, the peptide was named candidalysin (Moyes *et al.*, 2016). Thus, candidalysin links hyphal morphology and damage beyond physical rupture by continuous filamentous growth and provides further explanation for the significant role of filamentation in pathogenesis (Wilson *et al.*, 2016).

Interaction of *Candida albicans* with the Immune System

Immune cells are rapidly recruited during candidiasis and especially innate phagocytes are efficient and essential effector cells during fungal infections (Fig. 3) (Lionakis *et al.*, 2011; Duggan *et al.*, 2015; Lionakis, 2014). In fact, impairment of the immune system represents a risk factor for candidiasis, but not all patients suffering from disseminated *C. albicans* infections are obviously immunocompromised (Nolla-Salas *et al.*, 1997; Yapar, 2014; Guery *et al.*, 2009). To be a successful pathogen, *C. albicans* needs to be able to either prevent recognition or survive antimicrobial mechanisms employed by immune cells to a certain extent. As the

Fig. 3 Killing of *C. albicans* by professional human phagocytes. Killing of *C. albicans* by neutrophils and macrophages occurs intra- and extracellularly (IC/EC). IC: Internalization of *Candida* via phagocytosis leads to inactivation of fungus by ROS (yellow lightning) and host effector proteins. EC: Chemokines are released (purple glow) by activated phagocytes to recruit more phagocytes. Antifungal effector proteins are released into cell environment during degranulation. Neutrophils release extracellular traps (NETs) to entangle and kill *Candida*. Notably, *C. albicans* can outgrow macrophages, not neutrophils. Illustration by M.J. Niemiec.

immune response to *C. albicans* is addressed in detail in another module of this series, we will focus here on some of the mechanisms by which the fungus withstands elimination of the immune system.

The immune system can be roughly divided into cellular and humoral effector mechanisms. Humoral factors include antibodies, the complement system and antimicrobial peptides (AMPs). Antibodies are readily produced in humans and mice following exposure to *C. albicans* (Pitarch *et al.*, 2006, 2009, 2011; Mochon *et al.*, 2010) but naturally induced antibodies are considered to have only a limited protective effect (recently reviewed in Richardson and Moyes (2015)). The complement system and AMPs are evolutionary old and comprise two of the first lines of defense against invading microbes. Furthermore, AMPs are produced by mucosal epithelial cells even in the absence of a pathogenic threat and thereby control the commensal microbiota. Several AMPs, β -defensins, the cathelicidin LL-37 and histatin 5, have been shown to kill *C. albicans* in vitro (Chang *et al.*, 2012; Vylkova *et al.*, 2007a,b). It has furthermore been proposed that the reduced levels of histatin 5 observed in the saliva of HIV + patients contribute to the increased risk of these patients for oropharyngeal candidiasis (Khan *et al.*, 2013). Although this and the hypothesis that AMPs control fungal growth on mucosal surfaces in vitro appear plausible, only few studies have been conducted to address this experimentally (Liao *et al.*, 2017; Fan *et al.*, 2015). Nonetheless, *C. albicans* also seems to have evolved AMP resistance mechanisms, like inactivation through proteolytic cleavage of AMPs by Sap9 and Sap10 and inactivation by a secreted glycodomain of Msb2 (Meiller *et al.*, 2009; Puri *et al.*, 2012; Swidergall *et al.*, 2013; Szafranski-Schneider *et al.*, 2012). Tolerance to AMPs can furthermore be induced by induction of compensatory mechanisms, for example, Pbs2 via the Hog1 stress response pathway, or stabilization of mitochondrial integrity via Ssd1 and Bcr1 (Jung *et al.*, 2013; Argimon *et al.*, 2011). Similarly, *C. albicans* interferes with complement activation by various means (recently reviewed in Cheng *et al.* (2012) and Luo *et al.* (2013)), including proteolytic cleavage of active complement components by Saps and binding of host factors that regulate complement activation. To which extend these immune evasion mechanisms contribute to pathogenesis is not fully clear; however, complement defects render mice more susceptible to systemic candidiasis (Ashman *et al.*, 2003; Tsoni *et al.*, 2009). Furthermore, opsonization by complement enhances phagocytosis and fungal killing (reviewed in Rambach and Speth (2009)), thereby linking complement evasion to other survival strategies of *C. albicans*.

Professional phagocytes, especially neutrophils and monocytes/macrophages, constitute cellular components of the first line of defense against *C. albicans* (Basu *et al.*, 2008; Kullberg *et al.*, 1999; van Enkevort *et al.*, 1999; Romani *et al.*, 1996; van 't Wout *et al.*, 1988). Following recognition of the fungus via interaction of pattern recognition receptors (PRRs) with fungal surface components acting as pathogen-associated molecular patterns (PAMPs) (recently reviewed in Erwig and Gow (2016), Miramon *et al.* (2013), and Plato *et al.* (2015)), immune cells become activated and either phagocytose the pathogen or, in the case of neutrophils, can undergo degranulation or form neutrophil extracellular traps (NETs) via programmed cell death to release antifungal effector molecules (Gazendam *et al.*, 2016; Stephenson *et al.*, 2016) (Fig. 3). The cell wall composition and, more importantly, exposure of distinct components on the surface significantly influences the efficacy of recognition and the subsequent response induced; thus, cell wall modifications are one way by which *C. albicans* can influence recognition by phagocytes and, additionally, also phagosome maturation (Lewis *et al.*, 2012; Bain *et al.*, 2014). These mechanisms are discussed in detail below.

Phagocytosis requires physical uptake of the pathogen and is therefore influenced by size and shape. *C. albicans* hyphae can grow to a length that prevents complete phagocytosis (reviewed in Erwig and Gow (2016)). Therefore, the ability of *C. albicans* to form filaments affects the interaction with phagocytes. However, yeast cells can readily be phagocytosed and phagolysosome maturation creates a hostile environment characterized by reduced pH, a high concentration of AMPs, reactive oxygen and nitrogen species (ROS and RNS, respectively), hydrolytic enzymes and nutrient starvation (Erwig and Gow, 2016; Miramon *et al.*,

Fig. 4 Micronutrient acquisition by *C. albicans*. *C. albicans* imports, stores, and exports trace elements during its life-cycle. In the mammalian host, the availability of micronutrients is limited. Depicted are the transport systems for zinc and iron. Illustration by M. Kapitan.

2013). *C. albicans* is able to escape from macrophages by either triggering pyroptosis, a programmed cell-death pathway, or by affecting phagolysosome maturation, development of long hypha, and physical piercing of macrophages. Induction of pyroptosis by *C. albicans* is associated with hypha induction but does not require morphogenesis, but rather remodeling of the cell wall associated with increased 1,3 β -glucan exposure, and ergosterol (Uwamahoro *et al.*, 2014; Wellington *et al.*, 2014; O'Meara *et al.*, 2015, 2018; Koselny *et al.*, 2018). Furthermore, the fungal peptide toxin Candidalysin can trigger apoptosis (Kasper *et al.*, 2018).

Phagocytes typically produce significant amounts of ROS and RNS upon encountering *C. albicans* and oxidative mechanisms are important for killing of *C. albicans* (Aratani *et al.*, 2002; Sasada *et al.*, 1987; Vazquez-Torres *et al.*, 1996; Brothers *et al.*, 2013). The fungus responds by activating a general stress response that involves the protein kinase Hog1 and the more specific oxidative and nitrosative stress response pathway involving the transcription factors Cap1 and Cta4, respectively (Wang *et al.*, 2006; Alonso-Monge *et al.*, 2003; Arana *et al.*, 2007; Brown *et al.*, 2009; Smith *et al.*, 2004; Chiranand *et al.*, 2008; Patterson *et al.*, 2013; Day and Quinn, 2019). The activated stress response results in increased expression of detoxification systems (reviewed in detail in Erwig and Gow (2016), Dantas Ada *et al.* (2015) and Miramon *et al.* (2013)) that include superoxide dismutases (Sods) (Hwang *et al.*, 2002; Frohner *et al.*, 2009; Miramon *et al.*, 2012), catalase 1 (Nakagawa *et al.*, 2003; Wysong *et al.*, 1998), a glutathione-based system including glutathione peroxidases and reductases (Enjalbert *et al.*, 2007; Fradin *et al.*, 2005; Rubin-Bejerano *et al.*, 2003; Chaves *et al.*, 2007; Yadav *et al.*, 2011; Miramon *et al.*, 2014), and flavodoxin-like proteins (Li *et al.*, 2015), that are protective against oxidative stress. Resistance against nitrosative stress depends on the flavohemoglobin NO scavenger Yhb1 (Ullmann *et al.*, 2004). Upon phagocytosis, *C. albicans* furthermore upregulates certain metabolic pathways, including gluconeogenesis, enzymes for the utilization of alternative carbon sources, β -oxidation of fatty acids and the glyoxylate cycle, whereas glycolysis and protein synthesis are downregulated (Lorenz *et al.*, 2004; Fradin *et al.*, 2005). As the phagosome is generally considered to be poor in nutrients, this metabolic adaptation contributes to survival of the fungus in this specific environment (Fernandez-Arenas *et al.*, 2007; Miramon *et al.*, 2012). Finally, the upregulation of uptake systems for trace metals (discussed in detail below, see Fig. 4) by phagocytosed *C. albicans* cells likely contributes to overcome restriction of these micronutrients within host cells (Lorenz *et al.*, 2004).

The Cell Wall as a Dynamic Factor in *Candida*-Host Interactions

As the outer layer of the cell, the cell wall and associated proteins present the structures that mediate contact of *C. albicans* with the environment and host cells. While on the one hand providing the major outer physical structure for the cell and mediating resistance to adverse environmental conditions, the cell wall is also presenting pathogen-associated molecular patterns (PAMPs) that are recognized by PRRs on professional and associate immune cells (recently reviewed in Erwig and Gow (2016), Miramon *et al.* (2013), Plato *et al.* (2015), Barreto-Bergter and Figueiredo (2014), and Snarr *et al.* (2017)). Thus, the cell wall is critical for host-pathogen interactions of *C. albicans*. The fungal cell wall consists of different β -glucans, chitin and chitosan, which are located in an inner layer, and mannans attached to proteins in an outer layer (for details see Free (2013)). Most of the cell wall molecules are carbohydrates, which all contribute to immune recognition (reviewed in detail by Netea *et al.* (2008), Gow and Hube (2012), Zheng *et al.* (2015b), Plato *et al.* (2015), Becker *et al.* (2015), Erwig and Gow (2016), and Snarr *et al.* (2017)). The receptors involved in recognition and the response of immune cells differs depending on the cell wall moiety that is recognized: β -1,3 glucan interacts with the C-type lectin Dectin-1, which triggers a strong inflammatory response (Brown, 2011; Cheng *et al.*, 2011). Mannans can be recognized by Toll like receptors (TLRs), the Mannose Receptor DC-SIGN, Mincle and Galectin-3 (Netea *et al.*, 2008, 2006; Barreto-Bergter and Figueiredo, 2014), likewise inducing a proinflammatory response which is, in comparison to β -1,3 glucan, less pronounced (Gow and Hube, 2012). Chitin is sensed by NOD2, TLR9 and the mannose receptor, but in contrast to the other components can reduce inflammatory responses (Mora-Montes *et al.*, 2011; Wagener *et al.*, 2014). Thus, the relative exposure of the different carbohydrates determines the quality and quantity of subsequent immune responses. This is exemplified in studies of *C. albicans* mutants with defects in mannosylation which lead to increased exposure of inner cell wall components, resulting in altered interaction with immune cells (reviewed in Hall and Gow (2013) and Diaz-Jimenez (2017)).

Importantly, the cell wall composition and relative exposure of the different carbohydrate components is highly dynamic and influenced by the morphological state, environmental conditions and the interaction with immune cells (recently reviewed in Hall (2015)). Yeast and hypha differ in the types of glucan (Lowman *et al.*, 2003, 2014) and the amount of chitin, with chitin being more abundant in hypha (Munro *et al.*, 1998). Furthermore, the distribution of chitin differs; while it is found along the cell wall of hypha, it is concentrated at the bud scar in yeast (reviewed in Gow *et al.* (2012)). Furthermore, some mannoproteins are differentially expressed depending on the morphology, e.g., hypha-specific proteins like Hwp1 and Als3 (reviewed in Sundstrom (1999) and Trevijano-Contador *et al.* (2016)) and the mannan composition in yeast and hypha is different (Shibata *et al.*, 2007). As a consequence of these differences, immune cells respond differently to yeast and hypha (reviewed in more detail in Gow *et al.* (2011), Jacobsen *et al.* (2012), Erwig and Gow (2016), and Trevijano-Contador *et al.* (2016)).

The environment influences the cell wall composition and structure. Mannan structures (Kruppa *et al.*, 2011; Lowman *et al.*, 2011; Ene *et al.*, 2012) and the levels of glucan and chitin (Ene *et al.*, 2012), for example, vary depending on the culture conditions. As mentioned above, both pH and hypoxia affect the exposure of β -glucan (Sherrington *et al.*, 2017; Pradhan *et al.*, 2018; Lopes *et al.*, 2018). Lactate induces active β -glucan masking while cell wall stress induced by the antifungal echinocandins leads to increased chitin and enhanced β -glucan exposure both in vitro and during in vivo treatment (Walker *et al.*, 2008; Wheeler *et al.*, 2008; Lee *et al.*, 2012; Ballou *et al.*, 2016). Importantly, in the absence of antifungals, unmasking of β -glucan also occurs during systemic candidiasis in mice as a result of active cell wall remodeling in response to damage by neutrophil extracellular traps (Hopke *et al.*, 2016). Chitin can also be upregulated during infection, affecting recognition by Dectin-1, a phenomenon that varies between different *C. albicans* strains (Marakalala *et al.*, 2013). Increased chitin in *C. albicans* is furthermore associated with reduced virulence in a systemic mouse model (Lee *et al.*, 2012), highlighting the importance of the cell wall and its dynamic modifications for the interactions *C. albicans* with its host.

The Influence of Macronutrients on *Candida*-Host Interaction

As both a commensal and a pathogen, *C. albicans* can thrive at different anatomical sites. These differ not only in pH, oxygen levels and host defense systems but also regarding the quality and quantity of available carbon and nitrogen sources. Its success at the different niches suggests that *C. albicans* is metabolically versatile and has evolved means to assimilate a range of nutrient sources. Furthermore, the dissemination into various tissues during systemic infection requires fast adaptation to local nutrient availability. Indeed, *C. albicans* can utilize a vast variety of different sugars and amino acids (Brunke and Hube, 2013; Miramon and Lorenz, 2017) and a range of secreted hydrolytic enzymes contributes to the liberation of nutrients from complex molecules (Brunke and Hube, 2013; Naglik *et al.*, 2004; Schaller *et al.*, 2005). Complex regulatory networks mediate the response of *C. albicans* to nutrient starvation or alterations in the available carbon or nitrogen sources, leading to altered expression of hydrolases, transporters and metabolic pathways like gluconeogenesis, glycolysis or fatty acid β -oxidation (Barelle *et al.*, 2006; Askew *et al.*, 2009; Morschhauser, 2011; Ramachandra *et al.*, 2014; Sabina and Brown, 2009; Lee *et al.*, 2013). In comparison to the related baker's yeast *Saccharomyces cerevisiae*, substantial transcriptional and post-translational rewiring has occurred in *C. albicans*, contributing to the metabolic flexibility of *C. albicans* (Whiteway *et al.*, 2015; Sandai *et al.*, 2012; Ramirez and Lorenz, 2007).

In addition to providing the necessary energy for fungal survival, growth, and production of effector molecules, metabolic adaptation is directly linked via transcriptional networks to the expression of different fitness and virulence attributes such as morphogenesis, stress resistance, adhesions, and hydrolytic enzymes (Han *et al.*, 2011). Cell wall composition is also influenced by nutrients, especially carbon metabolism, and thereby metabolism indirectly influences the interaction with immune cells (recently reviewed in Hall (2015)). One well studied example is the growth of *C. albicans* on lactate in comparison to glucose and the changes caused by this. While most growth media used in the laboratory are rich in glucose, glucose availability is limited within the host. Thus, *C. albicans* has to use alternative carbon sources such as lactate. Growth on lactate in vitro led to alterations in cell wall architecture and secretome, with consequences for adhesion, stress resistance, and interaction with immune cells: Lactate grown cells were phagocytosed less by macrophages while fungal escape was enhanced; at the same time lactate-grown *C. albicans* cells induced more IL-10 but less IL-17, thereby leading to a reduced proinflammatory response (Ene *et al.*, 2012, 2013). As a consequence, fitness of lactate-grown *C. albicans* cells in vivo was enhanced (Ene *et al.*, 2012).

Due to the link between metabolism and fitness/virulence traits, the adaptation of *C. albicans* to different environments and nutrient availability within the host simultaneously affects expression of virulence factors (recently reviewed in Brown *et al.* (2014)). This linkage of metabolic responses to environmental clues and virulence can be interpreted as "adaptive prediction" (Mitchell *et al.*, 2009), by which the availability of distinct nutrients serves as a clue for further subsequent environmental changes, e.g., attack by immune cells following translocation into the blood stream, leading to oxidative stress due to ROS production. From an evolutionary perspective, this linkage is likely to be highly advantageous to the fungus and likely contributes to its success in diverse anatomical niches both as a commensal and a pathogen. For more information and a summary of the open questions, we refer the readers to the review by Brown *et al.* (2014).

Acquisition of Micronutrients by *C. albicans*

Micronutrients are as essential for microbial growth as carbon- and nitrogen sources. Trace metals such as iron, zinc, copper, and manganese are essential co-factors in enzymes and stabilize three-dimensional protein structures (Waldron *et al.*, 2009; Palm-Espling *et al.*, 2012). However, their free availability in the host is limited by sequestration and binding to host molecules. Host-mediated nutrient depletion from invading pathogens is also termed 'nutritional immunity,' a mechanism that has gained increased attention in recent years, and is therefore described in some detail below.

Every aspect of nutritional immunity, from the host or pathogen perspective, reflects the co-evolutionary nature of these interactions. Best studied is the competition for iron (see also a recent review by Fourie *et al.* (2018)), but most concepts apply to all transition metals in eukaryotes (Sutak *et al.*, 2008; Weinberg, 1975). In the host, iron is mainly kept intracellular – free iron is practically unavailable in blood or other extracellular liquids, with exception of the gut. Iron is bound to transferrin in plasma and lactoferrin in external secretions. However, in order to grow within the host, microbial pathogens cope with these limitations. In case of direct physical contact between the host iron source and the pathogen, host iron-retaining proteins might be manipulated to release their iron load into the extracellular environment for uptake. Secondly, many bacteria and fungi secrete siderophores: Small molecules with exceptionally high iron affinity that free iron from host proteins followed by resorption into the pathogen cell. In response, mammals produce lipocalin-2, to intercept siderophores. This can in turn be counteracted by many pathogens which disguise their siderophores by glycosylation (Sutak *et al.*, 2008). Iron is a common co-factor in enzymes and one of the most important direct functions of iron during host-pathogen interactions is likely the detoxification of H_2O_2 by the iron-dependent heme-enzyme catalase (Hamilton and Holdom, 1999). Iron uptake in *C. albicans* occurs by a reductive and the non-reductive mechanism (Waldron *et al.*, 2009; Almeida *et al.*, 2009) (Fig. 4). In a nutshell, the high affinity reductive uptake system functions via the interplay of three enzymes. A reductase (Fre) converts ferric Fe^{3+} to ferrous Fe^{2+} . The actual uptake is mediated by a permease (Ftr) and a multicopper ferroxidase (Fet). *C. albicans* relies on this pathway to acquire iron from ferritin and transferrin (Knight *et al.*, 2005; Almeida *et al.*, 2008). Probably due to functional redundancy due to gene expansion of the reductases and multicopper oxidases, only the permease Ftr1 has been shown to be crucial in blood stream infections by *C. albicans*. Non-reductive Iron uptake is based on the import of iron-containing proteins, namely, hemoglobin/heme (recently reviewed by Roy and Kornitzer (2019)) and siderophores. *C. albicans* has receptors for heme (e.g., Rbt5p), but also for ferritin (reductive uptake). The ferritin receptor and adhesin Als3 is expressed only by hyphae (Almeida *et al.*, 2008). Siderophores are not produced by *C. albicans*, but they can be utilized as an iron source even if produced by other microbes (Almeida *et al.*, 2009).

In contrast to other sites in the human body, the gut is probably the only site where microbes encounter high iron levels. Accordingly, as a colonizer of this niche, *C. albicans* is able to adapt not only to iron limitation but also to relatively high iron concentrations. To do so, an intricate system of three transcriptional regulators has evolved that controls iron uptake in *C. albicans* (Polke *et al.*, 2015; Blankenship and Mitchell, 2011). The transcriptional repressor Sfu1 and the virulence regulator Hap43 dampen iron uptake and Sfu1 is required for persistence of *C. albicans* in the gut. In contrast, during blood stream infections, when iron is limited, iron uptake is upregulated by Sef1, a process essential for virulence in the systemic mouse model (Chen *et al.*, 2011). Sfu1 represses Sef1, thereby interconnecting the response to low and high iron and adaptation to distinct niches in the host.

Uptake of iron and copper are very tightly connected. The ferroxidase (Fet) is actually a copper-dependent enzyme, and the iron reductases (Fre) are indeed ferric/cupric reductases that reduce Cu^{2+} to Cu^{1+} through the oxidation of Fe^{2+} to Fe^{3+} , and vice-versa (Niemiec, 2015). Reduced Cu^{1+} is taken up by Cu transporters (Ctr). Ctr1 and Ctr3 are plasma membrane-localized, Ctr2 is vacuolar – and all three transport towards the cytosol. Interestingly, the number of CTR copies varies between fungal species and might affect virulence due to an effect on, e.g., hyphal growth (Ding *et al.*, 2014). During infection, pathogens face copper starvation as well as copper intoxication. For example, excess copper has been described as a mode of action against intraphagosomal *Mycobacteria* in macrophages (Rowland and Niederweis, 2012). Therefore, copper export and copper detoxifying metallothioneins are important to maintain copper homeostasis. Metallothioneins are conserved in prokaryotes and eukaryotes. A potential role in virulence was demonstrated in *Cryptococcus neoformans*, a facultative intracellular fungal pathogen, but not yet in *C. albicans*. However, *C. albicans* is known to export excess copper, indicating that fungi are primed to resist potential copper poisoning in vivo (Ding *et al.*, 2014). At the same time, copper is essential for pathogenic survival. Most fungal SODs, crucial to withstand superoxide stress, have copper in their active site. In *C. albicans*, Sod1, Sod4, and Sod6 are copper/zinc-dependent, Sod5 was recently described to be a Cu-only SOD (Gleason *et al.*, 2014). *C. albicans* extracellular Sod4 and Sod5 were demonstrated to detoxify superoxides produced during interactions with macrophages (Frohner *et al.*, 2009).

Of all metal-containing enzymes, 9% use zinc – so zinc is the second most abundant metal cofactor after manganese (Waldron *et al.*, 2009). Further, zinc stabilizes zinc-finger domains, a function that is especially important in eukaryotic organisms (Decaria *et al.*, 2010). Several studies have demonstrated the importance of zinc in pathogenic and non-pathogenic fungi. *C. albicans* is very sensitive to zinc starvation. Zinc can actually be the limiting factor if all other nutrients are available (Soll *et al.*, 1981; Bedell and Soll, 1979). Zinc acquisition in fungal pathogens is mediated by a small number of proteins and is conserved in *C. albicans* (Fig. 4): Zinc enters the cytoplasm via the Zrt plasma membrane transporters (CaZrt1, CaZrt2). From there, zinc can be transported further into the vacuole through ZnT transporters (in *C. albicans*: Zrc1). In return, zinc can be mobilized from the vacuolar pool by Zrt exporters (CaZrt3). Interestingly, no cellular zinc exporter has been described in fungi, yet. The homeostasis of zinc is regulated on two levels: the expression of Zrt importers, controlled by Zap1, and zinc import and export from subcellular organelles (Wilson *et al.*, 2012), resulting in biphasic zinc compartmentalization which is essential for virulence (Crawford *et al.*, 2018). Vacuolar storage might be especially important during infection, since it allows proliferation even under zinc-restricting conditions

(Simm *et al.*, 2007). In addition, *C. albicans* uses a zincophore system – a secreted protein that sequesters zinc from host cells and re-associates with CaZrt1 to deliver zinc to the fungal cell: Pra1 (Citiulo *et al.*, 2012). The expression of Pra1 is repressed under acidic conditions, but induced under zinc starvation or at neutral/alkaline pH (Citiulo *et al.*, 2012). Remarkably, Pra1 is not only beneficial for the fungus, it is actually immunogenic and immune-modulatory (Wilson, 2015). Amongst many functions, Pra1 can serve as a ligand to neutrophil integrin receptor $\alpha M\beta 2$ and promote neutrophil killing (Soloviev *et al.*, 2007). Probably due to this “side effect,” Pra1 is not conserved in all pathogenic fungi (Wilson, 2015). Zinc is furthermore important for biofilm formation, and involved in tolerance to intrinsic oxidative stress by the cytoplasmic Sod1 (Wu *et al.*, 2009). Sod1 is a Cu/zinc superoxide dismutase (SOD). Notably, the cell surface superoxide dismutases Sod4p and Sod6p that are crucial to survive host-derived ROS, have Cu/zinc as their active site (Frohner *et al.*, 2009).

In non-plant eukaryotes, manganese function is restricted to mitochondrial enzymes, including Sod2 and Sod3. The human host restricts access to manganese by releasing calprotectin that is capable of binding manganese and zinc (Kehl-Fie *et al.*, 2011; Sohnle *et al.*, 2000). Furthermore, manganese (and iron) are actively depleted from the macrophage phagosome (Kehl-Fie and Skaar, 2010). Manganese restriction is important during bacterial infections, but its role during fungal pathogenesis requires more investigation (Corbin *et al.*, 2008; Kehl-Fie *et al.*, 2011; Posey and Gherardini, 2000).

C. albicans Morphology – Does it Determine the Difference Between Commensalism and Infection?

As mentioned throughout the previous parts, the formation of filamentous growth forms during morphogenesis is generally thought to be essential for *C. albicans* virulence. This concept is based on the observation that *C. albicans* mutant strains locked in either the yeast or hyphal form were attenuated in their virulence in murine infection models (Lo *et al.*, 1997; Braun *et al.*, 2000, 2001; Murad *et al.*, 2001). Given that hyphae have the ability to physically penetrate host cell barriers and hyphae formation is associated with production of candidalysin (Brand, 2012; Moyes *et al.*, 2016), it appears obvious that hyphae formation significantly affects the ability of *C. albicans* to penetrate tissue, damage host cells and cause disease. However, hyphae formation is co-regulated with several virulence-associated factors, leading to rearrangement of the cell wall and thereby affecting the response of immune cells, and is further associated with stress response and metabolism (Inglis and Sherlock, 2013; Dantas Ada *et al.*, 2015; Monge *et al.*, 2006; O'Connor *et al.*, 2010). It is thus difficult to determine to which extend the formation of hyphae per se contributes to virulence (Kumamoto and Vines, 2005). Most likely, both, yeast and hyphae, play distinct roles during the different steps of *C. albicans* infections (Gow *et al.*, 2002; Kumamoto and Vines, 2005; Saville *et al.*, 2003).

While invasive growth and host damage are intrinsically linked during infection, commensalism is characterized by a balance between host and fungus that does not cause host damage (Gow and Hube, 2012). Interestingly, genetic analyses revealed that colonization of the gut is associated with significant expression levels of hypha-associated gene expression, such as *EFH1*, *ECE1*, *RBT4*, and *RBT1* in yeast cells (d'Enfert, 2009; Doedt *et al.*, 2004; Rosenbach *et al.*, 2010; White *et al.*, 2007). Thus, transcriptional programs that were previously considered to be morphology-associated based on in vitro observations might be uncoupled from the filamentation program under distinct environmental conditions. Furthermore, *ECE1*, the gene encoding for candidalysin and required for host cell damage, is upregulated in the gut. This raises the question whether growth as yeast in the gut truly reflects a benign, commensal transcriptional program and whether separate commensal and pathogenic transcriptional programs exist. The fact that *C. albicans* intestinal colonization requires factors contributing to survival in phagocytes (Tan *et al.*, 2019), and that colonization stimulates innate immune mechanisms pathogens (Tso *et al.*, 2018; Shao *et al.*, 2019) suggests active interaction with the immune system; in combination with the advantage of yeast over filamentous morphologies in the gut, the yeast morphology in the gut is likely to be the consequence of complex interactions between host, intestinal environment, and *C. albicans*. Factors that have so far been only associated with *C. albicans* infections may be required for fungal survival in the gut. Indeed, recent gene network analyses of transcription factors required for gut colonization and/or fitness during systemic infection revealed several connections between the regulons of transcription factors important for either commensalism or virulence (Perez and Johnson, 2013).

Further research directed at a better understanding the entire *C. albicans* biology, not only as a pathogen but also as a commensal on different mucosa, is required to decipher what it is exactly that makes this fungus a successful member of the human microbiota. Hopefully, this will contribute to eventually elucidate the specific factors that predispose patients to disseminated candidiasis.

Glossary

Allele A variant of a locus.

Auxotrophy Inability of an organism to grow in the absence of a given organic compound.

Chemokines Type of cytokines that attracts specific celltypes to the site where they are secreted.

Clade Evolutionary term for a group of organisms including their common ancestor and all its descendants.

C-type lectin A type of lectin that requires Ca^{2+} for proper function.

Cytokine Small proteins that are secreted by various type of cells and play role in communication and interaction between cells.

Dectin-1 A C-type lectin playing important role in fungal recognition.

Desaturase An enzyme responsible for converting saturated chemical bonds to unsaturated ones.

Diploid A term used for organisms possessing two copies of each chromosome.

Endothelium Thin layer of endothelial cells covering the inner wall of blood – and lymphatic vessels.

Epithelium Thin layer of epithelial cells covering the inner and outer surfaces of the organs.

Ergosterol A type of sterol found in the fungal cell membrane to increase rigidity.

Glucan A D-glucose polymer in the fungal cell wall.

Heterozygosity A state of being heterozygous.

Heterozygote/ Heterozygous The organism possesses two different alleles in a given locus.

Homology Similarity of biological properties between species derived from the same ancestor.

Homozygote/ Homozygous The organism possesses the same alleles in the given locus.

Hybrid The resulting descendant of mating between two different species.

In silico Any approach (search, calculation, prediction, etc.) that utilizes a computer.

In vitro Any experiment performed outside of a living organism.

In vivo Any experiment performed on a living organism.

Lectin A protein that recognizes and binds carbohydrate molecules.

Lipase An enzyme that degrades fatty acids via hydrolysis.

Locus A given region of a genome.

Lysosome A membrane-bound organelle filled with hydrolytic enzymes in animal cells.

Macrophage Antigen presenting phagocyte in the tissues.

Mannan (O-, N-linked) A glucose polymer consisting of a linear backbone (α -1,6-bonds) with possible (α -1,2- or

α -1,3-bonds) branches. It can be attached to –OH groups of Serine or Threonine of proteins that is called O-linked mannan, or to –NH₂ group of Asparagine that is known as N-linked mannan.

Mating (yeast) A well regulated process by which two individual cells (belonging to the opposite mating type) fuse together.

Mb Megabase, unit of the size of DNA. 1 megabase is 1.000.000 bases.

Meiosis A type of cell division, where the initial chromosome number (characteristic to the parent cell) is halved (in the daughter cell).

MIC Minimum inhibitory concentration is the lowest concentration of a specific drug that inhibits the growth of the microbe of interest.

Mitochondrion An organelle in the eukaryotic cell responsible for providing energy.

Mitosis A type of cell division, where the initial chromosome number (characteristic to the parent cell) does not change (in the daughter cell).

Neutropenia A condition where the concentration of neutrophil granulocytes is less than $1500 \cdot \mu\text{l}^{-1}$.

Neutrophil granulocyte Short-lived white blood cells being present in the largest number in the blood of most mammals.

Null-mutant A strain of an organism lacking both alleles of a given locus.

Onychomycoses Infection of the nails caused by a fungus.

Orthology (genome) A type of homology where the homolog region is defined across species.

Paralogy (genome) A type of homology where the homolog region is defined in one species. It is typically represented by gene duplications.

PBMC Peripheral blood mononuclear cell, any blood cell possessing a round shaped nucleus.

PCR Polymerase chain reaction, a method used for multiply a specific region of the genome or DNA sequence.

Phagocyte A type of cells in the body that is capable of engulfing various organic or inorganic particles (fungus, bacteria, cell debris etc.).

Phagosome The organelle formed as a result of phagocytosis.

Phospholipases Enzymes responsible for hydrolyzing ester and ether bonds of phospholipids.

Phylogenetic reconstruction An *in silico* process by which the most probable relationship between species can be defined.

Plasmid A circular extrachromosomal element.

Primer A single oligonucleotide that act as starting point for DNA synthesis during PCR.

Promoter A DNA region found before a gene. This is where transcription factors can bind and therefore determine whether a gene is turned on or off.

Prototroph An organism that is capable of growing in the absence of organic nutrients.

QRT-PCR Quantitative real-time PCR, a PCR based method to determine the amount of a desired nucleotide sequence.

Receptor A protein that can receive and transfer chemical – or physical signals from the environment to promote a regulated cell response.

Recombinase An enzyme catalysing the recombination procedure.

Recombination A regulated process where different regions of the chromosomes are combined.

SNP Single nucleotide polymorphism or point mutation. A type of alteration in the nucleotide sequence where only one nucleotide is changed compared to a reference sequence.

Tetraploid A term used for organisms possessing four copies of each chromosome.

T_h cell Special type of immune cell being responsible for regulating the immune response by secreting specific cytokines.

Transcription factor Proteins that regulate the transcription.

Transcription A process by which the information encoded by a gene is converted into RNA.

Wild-type Any isolate without a genetic modification.

Candida parapsilosis Sensu Lato – General Introduction

Candida parapsilosis sensu lato species are diploid yeasts belonging to the so-called CUG clade of the Class *Saccharomycetes* (Division of *Ascomycota*). The term “*C. parapsilosis sensu lato*” refers to three very closely related but distinct species: *C. parapsilosis sensu stricto*, *C. orthopsilosis*, and *C. metapsilosis*, formerly known as *C. parapsilosis* Group I, II and III, respectively. Their genome sizes range between ~12.6–13.3 Mb and encode ~5700–6300 genes. Although they conserve remnants of mating related genes in their genomes, no complete sexual cycle has yet been observed in this group. Instead, recent results suggest that genetic diversity is increased through hybrid formation. These species are generally considered as human commensals, often associated with healthy human skin and mucosa. However, in the setting of immune compromise, these fungi cause illnesses ranging from mild superficial or mucosal infections to life-threatening systemic diseases. Strikingly, *C. parapsilosis sensu stricto* has a strong predilection for disease in low and very low birth weight neonates and is responsible for numerous outbreaks in neonatal intensive care units. Additional predisposing risk factors for disease from these pathogens include the use of intravenous catheters, antibiotics, neutropenia, HIV infection, cancer therapy and prolonged hospitalization. After identification, azole derivatives are generally administered, alternatively amphotericin B may be used or, if susceptible, echinocandins. Although significant advances in the understanding of the pathobiology of these yeasts have been made, there remain many questions regarding the specific tools that they harness to enable human infection. The virulence factors that have been identified to date, include adhesins and secreted hydrolytic enzymes (lipases and proteinases). In turn, host receptors involved with recognition and interaction with these yeasts include Toll-like receptor 4 (TLR4), Dectin-1, and Galectin-3. Additional insights have suggested that *C. parapsilosis sensu stricto* can modulate the host immune response by inhibiting the Th1/Th17 host response and inducing antigen production to hide from the host immune system. There are many unexplained questions regarding the biology of *Candida parapsilosis sensu lato* species, but their increased medical importance over the past two decades has resulted in numerous active investigations intended to elucidate a deeper understanding the pathogenesis of these species in order to develop improved preventative and therapeutic strategies.

Candida parapsilosis Sensu Lato Complex – History

The evolution of the nomenclature of the *Candida parapsilosis sensu lato* species is somewhat convoluted and emerged out of a lack of scientific tools as well as the absence of standardization of scientific naming. Moreover, communication between doctors, biologists and other scientists was very limited and ponderous in the late 1800s and early 1900s. At that time macroscopic/microscopic morphology and the capability of an isolate to grow or not to grow on/in different mediums were the basis for species identification (Castellani and Chalmers, 1919; Stovall and Bubolz, 1932; Ciferri and Redaelli, 1929). The limitation of these methods and the disarray of species naming are well represented by the publication of Ciferri and coworkers who found 121 synonym names for *Candida albicans* in the literature in 1938 (Ciferri *et al.*, 1938). In fact, the majority of *Candida* species were mostly described as *Monilia* in the literature 19th and the first half of the 20th century until the 1940s when a group of scientists proposed a fundamental change in the nomenclature based on the hosts these microbes infect. Since then, *Monilia* species were considered as plant pathogens and the name *Candida* was dedicated to yeasts infecting animals (Mackinnon and Artagaveytia-Allende, 1945; Skinner, 1947). There was also an attempt to standardize the classification process. Besides morphology, various cultivation methods were applied and fermentation properties were examined that helped avoid misidentification of the *Candida* species (Martin and Jones, 1940).

The first appearance of the name *Candida parapsilosis* in the literature was in 1932 by Langeron and Talice. However, this organism had actually been reported 6 years before by Pollacci and Nann in their scientific paper on a microbe called *Monilia*

onychophila, that later turned out to be *C. parapsilosis*. Unfortunately, many of these early reports are not available directly, but are known through references in subsequent publications (Talice, 1932; Martin and Jones, 1940; Talice, 1932). The earliest accessible publication is from 1928 written by a doctor named Ashford who described a patient suffering from diarrhea whose stool grew an interesting yeast. This microbe differed in its fermentation capabilities from the well known yeast at that time called *Monilia psilosis*, which had previously been isolated from stool and other patient samples. Ashford named this microbe *Monilia parapsilosis* and this is today known as *Candida parapsilosis* while *Monilia psilosis* is called *Candida albicans* (Ashford, 1928; Robin, 1923; Rogers, 1922).

C. parapsilosis gained importance in the 1970s when the number of medical case reports related to this yeast started to rise. Further reports underscored that the predilection for disease varied in *C. parapsilosis* compared to *C. albicans* as, for example, *C. parapsilosis* is often associated with neonatal candidiasis (Anonymous, 1977; Faix, 1983; Baley et al., 1986). It was during this time period that significant advances in molecular biology techniques occurred that facilitated the use of genetic markers and related methods for species characterization and identification. By applying techniques such as restriction fragment length polymorphism (RFLP) and random amplification of polymorphic DNA (RAPD), the genetic background of *C. parapsilosis* was revealed to have diversity as demonstrated by sequence variances in the internal transcribed spacers (ITS) as well as in mitochondrial DNAs and rRNA domains. These data led to *C. parapsilosis* being separated into three different groups, called Group I, II and III (Scherer and Stevens, 1987; Lehmann et al., 1992; Lin et al., 1995; Nosek et al., 2002b; Kurtzman and Robnett, 1998; Kurtzman and Robnett, 1997; Rycovska et al., 2004). In 2005, Tavanti and coworkers used a multilocus sequence typing (MLST) technique to more deeply molecularly characterize these three groups and their work suggested that the *C. parapsilosis sensu lato* group should be divided into three individual species: Group I became *C. parapsilosis sensu stricto*, Group II was renamed to *C. orthopsilosis* and Group III was called *C. metapsilosis* (Tavanti et al., 2005). The three species are impossible to distinguish based on macroscopic or microscopic characteristics. In general they are all incapable of fermenting maltose and present as round or elongated cells, which may form pseudohyphae (Ashford, 1928). Colonies are usually shiny, white or yellowish in color, but this feature depends on the media used for cultivation. The morphology of *C. parapsilosis sensu lato* colonies is very diverse (smooth, rough, snowball, crepe, crater and concentric) and can be influenced by compounds or chemicals used in the media (Enger et al., 2001; Laffey and Butler, 2005). The species grow well at 30°C and 37°C, but none grow at 42°C. The holotypes have similar minimal inhibitory concentration (MIC) values against antifungal agents, and they also do not differ in either their biofilm forming capabilities or sugar assimilation profiles. Since morphological characterization cannot distinguish between these species, molecular methods are applied for species identification. Standard identification approaches are based on the localization of single nucleotide polymorphisms (SNPs) in putative alanyl-tRNA synthetase and secondary alcohol dehydrogenase genes compared to the historically most ancient species, *C. parapsilosis sensu stricto*. Primer pairs have also been developed that do not amplify any fragment from *C. metapsilosis* and *C. orthopsilosis* genome (Tavanti et al., 2005).

Candida parapsilosis Sensu Lato – Epidemiology

The *Candida* strains that scientists studied in the 1940–50s were mostly isolated from oral, vaginal and stool samples and the outcome of these illnesses were rarely fatal (Seelig, 1966). Although *C. albicans* was the most abundant among them, some other, so-called non-*albicans* species were also represented. The emergence of *Candida* species as a significant human pathogen began in the decade of “Penicillin era”, when healthcare workers began to encounter super-infections. This term was used when a patient was admitted to a hospital with a bacterial infection and was treated with an antibiotic that eliminated the pathogen, but a secondary infection occurred (a.k.a. a super-infection, an infection caused a microbe other than the original one). One of the early well-known pathogens responsible for super-infections was *Staphylococcus aureus* but later fungi also started to emerge (Colgan, 1956; Scales et al., 1956; Woods et al., 1951). The possible connection between the use of broad-spectrum antibiotics and super-infection was first discussed in 1949 by Harris, who proposed that antibiotic drugs eradicated the microbes causing the presenting disease, but also eliminated or at least attenuated normal gut colonizing bacteria facilitating the development of super-infections by certain organisms, such as *Candida* species (Harris, 1949). Other reports subsequently provided additional support for this concept of antibiotics disrupting homeostasis of normal flora (Bartels and Buchbinder, 1945; Pappenfort and Schnall, 1951; Janke, 1952; Huppert et al., 1953; Sharp, 1954). Moreover, experimental evidence was provided by Foley and Winter in 1949, who demonstrated that the administration of penicillin *in vivo* to chicken embryos enhanced the lethality of *C. albicans* clinical strains (Foley and Winter, 1949).

In addition to modification by antimicrobials, the general health of the host’s immune system was identified as a critical factor in resistance to *Candida*. Alterations in host immunity that facilitated *Candida* infection ranged from the increased access to the bloodstream via intravenous catheters to devastation of host effector cells through primary or secondary immune destruction. Along this line, by the late 1970s and early 1980s, two independent effects leading to immunodeficiency were recognized as being closely connected to candidiasis: (1) organ transplantation associated with artificial attenuation of the immune system to avoid organ rejection and (2) patients with acquired immunodeficiency syndrome (AIDS) caused by the human immunodeficiency virus (HIV) (Sanger et al., 1962; Klein et al., 1984). The increasing rates of *Candida* species among immunocompromised patients and their association with nosocomial infections resulted in a fundamental change in research priorities. Early publications in the *Candida* field had focused primarily on species identification, characterization and case reports, but the rapid increase in clinical cases expanded investigations into *Candida* virulence, pathogenesis and molecular characteristics. Infection models were established, the essential compounds required for growth were identified and the chemical properties of the cell wall were determined

(Salvin *et al.*, 1952; Eisman *et al.*, 1953; Gebhardt and Hill, 1956; Roth *et al.*, 1957; Johnson, 1954; Sikl *et al.*, 1964). Since *C. albicans* has long been the dominant *Candida* species causing systemic infections, most of these publications report results primarily on *C. albicans*; however, scientific papers from the 1950s began to explore other *Candida* species, including *C. tropicalis*, *C. krusei*, *C. glabrata* and *C. parapsilosis* (De Eshougues *et al.*, 1951; Monod *et al.*, 1956; Rotter and Staib, 1958; Rook and Brand, 1950; Wickerham, 1957; Manchester and Georg, 1959).

C. parapsilosis sensu lato species are associated with humans (Weems, 1992). Interestingly, although *C. parapsilosis sensu stricto* has also been isolated from non-human sources like plants, seawater and soil, there have been no environmental *C. orthopsilosis* or *C. metapsilosis* strains isolated to date, but this does not necessarily mean that these species do not have a niche unrelated to humans (Fell and Meyer, 1967). There are differences in tissue colonization by these species with *C. parapsilosis sensu stricto* and *C. orthopsilosis* colonizing normal skin, *C. parapsilosis sensu stricto* and *C. metapsilosis* oral mucosa and *C. parapsilosis sensu stricto* vaginal mucosa (Underhill and Iliev, 2014; Findley *et al.*, 2013; Ghannoum *et al.*, 2010; Nyirjesy *et al.*, 2005). However, they are opportunistic pathogens as local and systemic disease can arise from colonized tissues. In addition to the above described risks of immunodeficiency and use of antibiotics as predisposing factors for disease secondary to these species, prolonged hospitalization, intravenous catheters, indwelling medical devices, surgical interventions, malignancy, neutropenia and burn injuries are all associated with invasive infections (Law *et al.*, 1984; Pan *et al.*, 2012 and reviewed in Trofa *et al.*, 2008). Additionally, parenteral nutrition, intravenous lipid emulsion and intubation are also important risk factors for infections due to *C. parapsilosis sensu stricto*, particularly in neonatal disease (Saiman *et al.*, 2000). *C. parapsilosis sensu stricto* is the predominant species identified in clinical disease followed distantly by *C. orthopsilosis* and *C. metapsilosis* (Gomez-Lopez *et al.*, 2008; Lockhart *et al.*, 2008; Tay *et al.*, 2009; Mirhendi *et al.*, 2010; Orsi *et al.*, 2010; de Toro *et al.*, 2011). Nevertheless, *C. orthopsilosis* and *C. metapsilosis* species have been isolated from ascites fluid, cerebrospinal fluid, joint fluid, abscesses, lung, blood, skin, nail, urine, central venous catheter and from superficial candidiasis (Lockhart *et al.*, 2008; Chen *et al.*, 2010; de Toro *et al.*, 2011; Asadzadeh *et al.*, 2016; Feng *et al.*, 2012; Silva *et al.*, 2009a; Schroder *et al.*, 2016).

C. parapsilosis sensu lato species cause candidemia (fungemia caused by *Candida* species), which is a dangerous condition when the fungus gets into the blood and therefore can disseminate throughout the body. Interestingly there is a remarkable difference between *C. albicans* and *C. parapsilosis sensu stricto* in this process. *C. albicans* is a normal colonizer of the gut and the female genitals and is transmitted from mother to child during and shortly after birth (called vertical transmission) (Nucci and Anaissie, 2001; Tiraboschi *et al.*, 2010; Farr *et al.*, 2015). Thus, people who develop *C. albicans* candidemia are usually infected by the strain they are colonized with. In contrast, *C. parapsilosis sensu stricto* does not need to undergo colonization after adhesion to cause such a disease. These infections are often associated with hospital environments (nosocomial infections), where medical devices and healthcare workers contribute to the horizontal transmission of this yeast (discussed in Trofa *et al.*, 2008). Nosocomial acquisition of *C. parapsilosis* has been deemed responsible for 9%–39% of adult infections (reviewed in detail in Trofa *et al.*, 2008). There are relatively few reports of candidemia due to *C. metapsilosis* and *C. orthopsilosis* (Gomez-Lopez *et al.*, 2008; Chen *et al.*, 2010; Blanco-Blanco *et al.*, 2014; Constante *et al.*, 2014; Ziccardi *et al.*, 2015); however, this could be due to inaccurate speciation within the *C. parapsilosis sensu lato* group.

The clinical relevance and manifestations of *C. parapsilosis sensu stricto* range from superficial to disseminated infections. Fungal meningitis, arthritis, ocular and urinary tract infection rarely occur due to *C. parapsilosis sensu stricto*. Fungal peritonitis is also a rare, but serious condition with high mortality rate, mostly caused by *Candida* species, among which *C. parapsilosis sensu stricto* has been found to be responsible for 26%–34% of cases (Chen *et al.*, 2004; Wang *et al.*, 2000; Warady *et al.*, 2000; Manzano-Gayosso *et al.*, 2003). *Candida* species are the second or the third most common cause of fungal nail infection (onycomycoses) (Mugge *et al.*, 2006; Jayatilake *et al.*, 2009). Although globally *C. albicans* is the dominant species causing onychomycoses, *C. parapsilosis sensu stricto* is the most prevalent species of the genus in some regions (Mugge *et al.*, 2006; Mujica *et al.*, 2004; Segal *et al.*, 2000; Fich *et al.*, 2014). Vulvovaginal candidiasis is a condition that 50% of the women over 25 years of age will experience at least once. It is mostly caused by *C. albicans* (85%–95%) while *C. parapsilosis sensu stricto* varies between 1.2%–8.9% (Geiger *et al.*, 1995; Sobel, 2007; Nyirjesy *et al.*, 2005 and reviewed in Trofa *et al.*, 2008). *C. parapsilosis sensu stricto* is also the second most common cause of fungal endocarditis, with a mortality rate of approximately 50% (Martin *et al.*, 1979; Ellis *et al.*, 2001; Garzoni *et al.*, 2007). The most striking observation regarding *C. parapsilosis sensu stricto* epidemiology, however, is its remarkable tendency to cause disease in low birth weight (less than 2500 grams) premature infants (Cheng and Yu, 1970; Rubinstein *et al.*, 1975; Brunner, 1975; Gugnani *et al.*, 1978; Yarchoan *et al.*, 1979; English, 1972; Falagas *et al.*, 2010). As noted above, parenteral nutrition, intravenous lipid emulsion and intubation are major risk factors for neonatal *C. parapsilosis sensu stricto* disease (Saiman *et al.*, 2000). In this specific group of patients, the prevalence of *C. parapsilosis sensu stricto* varies between 15.5%–65.1% (reviewed in Trofa *et al.*, 2008). In these neonates, the infection can affect almost all the body sites including the lungs, urine, retina and central nervous system (Carter *et al.*, 2008). In one study of a 15 year period (from 1981 to 1995) the prevalence of candidemia increased by 10-fold in a neonatal intensive care unit in the USA, with *C. albicans* as the dominant species during the first 10 years, but *C. parapsilosis sensu stricto* was responsible for up to 60% of the cases in the last 5 years (Kossoff *et al.*, 1998). Although this is an extreme example, the dominance of *C. parapsilosis sensu stricto* is obvious as it was demonstrated by a large scale study published in 2013 focusing specifically on neonatal candidemia. The authors summarized the results of 37 publications and found the average proportion of *C. parapsilosis sensu stricto* of all neonatal *Candida* infection was 33.4%. The infection did not show a homogeneous geographic distribution, it varied between 19.1 and 35.7% among continents (Europe 19.1%, Asia 24.7%, South America 29.1%, North America 33.8% and Australia 35.8%). The average mortality rate among neonates was approximately 10% (reviewed in Trofa *et al.*, 2008; Pammi *et al.*, 2013). However, the data presented a reciprocal correlation between birth weight and mortality rate, i.e., lower

the birth weight the higher the mortality rate. The mortality rates among infants weighing less than 1500 grams varies between 20% and 45%, and those who recover frequently suffer from long-term neurodevelopmental issues (Benjamin *et al.*, 2006; Fridkin *et al.*, 2006; Benjamin *et al.*, 2010; Miranda *et al.*, 2012; Friedman *et al.*, 2000). *C. metapsilosis* and *C. orthopsilosis* are infrequently reported as causes of neonatal candidemia (Oliveira *et al.*, 2014). Despite the clear association of *C. parapsilosis sensu stricto* with neonatal invasive disease, the ability of this fungus to preferentially affect this specific patient population remains unresolved.

***Candida parapsilosis Sensu Lato* – Diagnostics and Treatment**

Until the early 1950s superficial and systemic *Candida* infections, independent of the species, were difficult to cure due to the lack of effective antimycotics (Duhig and Mead, 1951). The first antifungal drug available was nystatin that was followed by amphotericin B soon after (Hazen and Brown, 1950; Oura *et al.*, 1955; Sloane, 1955). These drugs are polyenes that function by destabilizing cell membrane ergosterol in fungi, causing an imbalance in ion homeostasis (reviewed in Ellis, 2002; Hammond *et al.*, 1974). These polyenes are challenged by their lack of absorption orally and their intravenous use is complicated by side effects, such as renal injury (Bell *et al.*, 1962; Giddings, 1962; Haber and Joseph, 1962). Nevertheless, amphotericin B was to the first antifungal that was able to cure systemic candidiasis, and newer formulations with less toxicity have been developed, particularly by admixing with lipids or intercalating the drug into liposomes (summarized in Dismukes, 2000). *C. parapsilosis sensu lato* isolates are susceptible to amphotericin B with very few exceptions, although *C. parapsilosis sensu stricto* is somewhat less susceptible than the other two members of the complex (Lockhart *et al.*, 2008; Silva *et al.*, 2009a; Ziccardi *et al.*, 2015; Lotfali *et al.*, 2016). Historically polyenes were followed by flucytosine (5-Fluorocytosine or 5-FC) in the late 1960s to treat candidiasis (Tassel and Madoff, 1968). This chemical is a fluorinated analogue of the base cytosine and can be uptaken by fungal cells. 5-FC itself does not possess antifungal activity however in the fungal cell it can be converted into derivatives inhibiting fungal RNA and DNA synthesis (Polak and Scholer, 1975; Waldorf and Polak, 1983). 5-FC has excellent oral bioavailability and can be effective in the setting of disseminated candidiasis (Tassel and Madoff, 1968). However, rapid resistance can occur with monotherapy, which limits the use of 5-FC (Hoeprich *et al.*, 1974; Ostrosky-Zeichner *et al.*, 2003). In the 1980s, azoles (that interfere with the ergosterol biosynthesis of fungi) became available and their ease of administration by the oral route has made them highly utilized (Sobel *et al.*, 1989). The azoles include ketoconazole, fluconazole, posaconazole, itraconazole, isavuconazole, and voriconazole. Of these, fluconazole is the most commonly used drug to treat *C. parapsilosis sensu lato* infections, since most of the isolates tested so far are susceptible (Pappas *et al.*, 2004). Although a publication from 2008 found that *C. parapsilosis sensu stricto* minimal inhibitory concentrations (MICs) were slightly lower than the ones of *C. orthopsilosis* and *C. metapsilosis*, a 2015 study established an opposite correlation (Ziccardi *et al.*, 2015; Lockhart *et al.*, 2008). These differences might be due to the limited sample numbers examined (especially in the case of *C. metapsilosis* and *C. orthopsilosis*) or it can be a geographical characteristic, but it is also possible that susceptibility is changing over time. At present, the echinocandins (anidulafungin, caspofungin, micafungin) are also frequently used prior to speciation of *Candida* identified in invasive disease (see Pappas *et al.*, 2016b). Echinocandins interfere with the β -1,3-glucan synthase 1, an enzyme responsible for cell wall biosynthesis of specific fungi, like *Candida*. *C. parapsilosis sensu stricto* displays a higher MIC value compared to *C. metapsilosis* and *C. orthopsilosis* as well as *C. albicans* (Ostrosky-Zeichner *et al.*, 2003; Pfaller *et al.*, 2006; Lockhart *et al.*, 2008). A possible explanation for this phenomena could be the diverse sequences of *FKS1* (the gene that encodes the synthase enzyme) orthologs in the three species (Garcia-Effron *et al.*, 2011). Moreover some authors reported strains of *C. parapsilosis sensu stricto* resistant to caspofungin (Ataides *et al.*, 2015; Ziccardi *et al.*, 2015). Due to the different mechanisms of these drugs, combination therapy utilizing antifungals with different mechanisms of action can be considered (Rex *et al.*, 2000; Vasquez *et al.*, 2002 and summarized in detail in Pappas *et al.*, 2004, 2016a).

Because of the different susceptible profiles of pathogens, accurate and rapid identification of the species is crucial for efficient antimicrobial therapy. To identify *Candida* species from clinical samples one can utilize molecular and non-molecular methods. The latter involves differential medias, carbohydrate assimilation/fermentation tests and microscopic examinations. Although these methods are relatively cost-efficient they are time consuming. There were also detection kits commercially available making these processes faster and more accurate but still the identification may take longer than one day. Molecular methods involving peptide nucleic acid – fluorescent *in situ* hybridization (PNA - FISH) designed to 26S RNA, polymerase chain reaction (PCR) applied alone or in combination with DNA digestion, quantitative real-time – PCR (qRT-PCR) with targeting dedicated genomic region of a specific pathogen were introduced, but these methods were much time intensive and costly (Rigby *et al.*, 2002; Flahaut *et al.*, 1998; Morace *et al.*, 1997; Maaroufi *et al.*, 2003). Due to the lack of special equipment and standardized protocols in many hospitals still non-molecular methods are in use (Hospenthal *et al.*, 2006 and reviewed in Silva *et al.*, 2012). More recently, techniques such as Luminex xTAG Fungal Analyte system, matrix-assisted laser desorption ionization – time of flight mass spectrometry (MALDI - TOF MS) and loop-mediated isothermal amplification (LAMP) methods are being utilized in some institutions due to their high specificity and sensitivity (Babady *et al.*, 2011; Buchan and Ledebor, 2013; Haas *et al.*, 2016; Trabasso *et al.*, 2015).

Candida parapsilosis Sensu Lato - Phylogeny

As noted, *C. parapsilosis sensu lato* species complex belongs to the Class *Saccharomycetes* (Division of *Ascomycota*/Kingdom *Fungi*) and they are members of the CUG clade, a group of yeasts that differs from most other organisms in how its members translate the CUG codon during protein synthesis. The universal codon usage CUG nucleotide triplet is generally translated to the hydrophobic amino acid leucine, but these fungi incorporate the hydrophilic amino acid serine instead (Santos and Tuite, 1995). The CUG clade also includes *Lodderomyces elongisporus* and *Debaryomyces hansenii* and certain *Pichia* species as well as other *Candida* species, like *C. albicans*, *C. dubliniensis*, *C. tropicalis* (Pryszcz et al., 2015). Computational analyses have revealed that *C. parapsilosis sensu stricto*, *C. orthopsilosis* and *C. metapsilosis* are a closely related species complex in the CUG clade irrespective of the genomic regions chosen or the methods applied for calculations. By changing these parameters, however, the topology of the *C. parapsilosis sensu lato* species might be different in one publication compared to another. For example using only internal transcribed spacer 1 (ITS1) (a short non-coding genomic region located between 18S and 5.8S rDNA coding sequences) in combination with neighbor joining for phylogenetic reconstruction, *C. orthopsilosis* and *C. metapsilosis* clustered together separately from *C. parapsilosis sensu stricto* (Tavanti et al., 2005). This topology was also found when the ITS1 - 5.8S rDNA - ITS2 region was the subject of analysis with the same approach (Robl et al., 2014) or when the partial sequences of more than 1000 genes were analyzed using a maximum likelihood method (Riccombeni et al., 2012). However, when this latter algorithm was applied for genomic sequences of mitochondrial proteins, the basal position of *C. metapsilosis* was established, while *C. orthopsilosis* and *C. parapsilosis sensu stricto* seem to be more closely related (Wu et al., 2009). Similar results were obtained by a recent analysis applying the sophisticated PhylomeDB pipeline for all the ortholog genes of the three species (Pryszcz et al., 2015).

Candida parapsilosis Sensu Lato – Genomics

Current methods allow for the whole genome sequencing of an organism within a few weeks. Understanding a species genome not only facilitates genetic manipulation, but the data can also be used for comparative analysis with other genomes to reveal genomic differences between species and even strains, and the data helps retrace evolutionary connections and trends. The genomes of *C. parapsilosis sensu lato* species complex conserves remarkable genetic evidences of how a species evolved on the way to becoming a human pathogen. Remarkably, all three members of the *C. parapsilosis sensu lato* group went through different evolutionary paths to become the pathogenic species that we know today. The first whole genome sequence available of the species complex was of *C. parapsilosis sensu stricto*. The genome of the clinical strain CDC 317 (isolated from a hand of a health care worker in the USA) was published in 2009 (Kuhn et al., 2004; Butler et al., 2009). This was followed by *C. orthopsilosis* and *C. metapsilosis* in 2012 and 2015, respectively (Riccombeni et al., 2012; Pryszcz et al., 2015). These three species are considered to be diploid organisms and they have not been observed to undergo either mating or meiosis. Mating requires two mating competent cells belonging to opposite mating type, as is a well described process in *Saccharomyces cerevisiae*. These types are determined by two loci in *S. cerevisiae* called mating type (MAT). The MAT locus can be either an “a” or an “α” idiomorph in this species (Haber, 2012). Homologous sequences of MATa and MATα idiomorphs can be found in other yeasts like *C. albicans* and they are also present (sometimes only partially) in the *C. parapsilosis* species complex where they are called mating-type-like (MTLa and MTLα) locus (Sai et al., 2011).

Candida parapsilosis Sensu Stricto – The Single

Although more than 200 isolates of *C. parapsilosis* have been genetically analyzed, no MTLα idiomorphs have been found; therefore, there is genetically no chance for mating. Not having been found of course does not mean it does not exist, maybe it is very rare, or it has a specific geographic preference. However, the complete lack of a mating competent strain encoding MTLα idiomorph in its genome is just one reason explaining why mating might not occur in this species. Besides, a1 gene encoded within the MTLa idiomorph turned out to be a pseudogene (possibly due to a recent event), therefore it is not functional (Sai et al., 2011; Logue et al., 2005). Many authors have reported on the poor genetic variability among different *C. parapsilosis sensu stricto* clinical isolates, which points to the fact that this species might be highly clonal, meaning that the originally environmental species adapted to the human host only one time with the isolates causing human disease representing descendants of the same ancient strain (Lasker et al., 2006; Butler et al., 2009; Tavanti et al., 2010). The first comprehensive whole genomic analysis of *C. parapsilosis sensu stricto* revealed molecular evidences suggesting that this transition might have actually happened more than once. The comparative genomic approach involved the reference strain CDC 317 and three newly sequenced strains: two environmental isolates (CBS 1954 from Italy and CBS 6318 from the USA), and one clinical strain GA1 (isolated from bloodstream infection in Hamburg, Germany) (Pryszcz et al., 2013; Butler et al., 2009; van Rij and Verona, 1949; Valach et al., 2012; Gacser et al. 2005). Pryszcz and coworkers established expansions of the arsenite transporter 3 (ARR3) gene (that encodes a protein required in baker's yeast to survive under high arsenic conditions) in clinical isolates (Ghosh et al., 1999). One can assume that an organism living on the human skin does not have to face the selection pressure of arsenite, as it is highly toxic to the host. Therefore, the increased number of this gene presumably provides evolutionary advantage in the environment but not in/on the host. According to the molecular analysis these genetic expansions in the two clinical isolates occurred independently, meaning that the two strains might have been created in nature. If this is true, the “environment to human” transition of *C. parapsilosis sensu stricto* might not have been

a unique event and might have happened at least twice (Pryszcz *et al.*, 2013). Further analysis established few (5147) SNPs and 40 copy number variations (including deletions and duplications) between the four strains. Predicted gene numbers and genome sizes varied (between 5665 and 6293 genes and 13.030 and 13.138 Mb) mostly due to copy number variations. Heterogeneous distribution of SNPs and the footprints of flanking regions of deletions suggest that recombination events likely happened in *C. parapsilosis sensu stricto* (Pryszcz *et al.*, 2013). This is in line with the finding of Fundyga and colleagues, who had proposed that the minor sequence variations in the sequenced alleles could have been introduced by recombination events (Fundyga *et al.*, 2004). All these results taken together describe a largely homogenous genome and (in evolutionary steps) a very young species (estimated age of the *C. parapsilosis sensu stricto* species is about 10⁶ years) (Pryszcz *et al.*, 2013; Fundyga *et al.*, 2004).

Candida orthopsilosis – Keep on Hybridizing

C. orthopsilosis species seems to consist of (at least) two different subspecies called Type 1 and Type 2. The latter is very likely formed due to a hybridization event. The signs of divergence and recombination within the species were described in 2005 and 2007 by Tavanti and coworkers by using RAPD and amplified fragment length polymorphism (AFLP) analysis (Tavanti *et al.*, 2005, 2007). Also in 2005, Iida and colleagues analyzed ITS sequences of *C. parapsilosis sensu lato* species, and identified two previously unknown groups of the complex. One was called Group IV, which showed the highest similarity to Group II (*C. orthopsilosis*) and one more group (named Group V) that seemed to be closely related to Group II and Group IV (Iida *et al.*, 2005). The genome of *C. orthopsilosis* (strain 90–125, a Type 2 isolate) was published in 2012. The 12.6 Mb genome contains 5700 protein-coding genes distributed on eight chromosomes (Riccombeni *et al.*, 2012). Based on the strains and sequences available, the genome of *C. orthopsilosis* is the only one in the complex so far that conserves evidence of mating in terms of MTL loci. This was established by Sai and colleagues, who investigated 16 *C. orthopsilosis* isolates and found both MATa/MATa (9 out of 16), MATα/MATα (5 out of 16) homozygous and MATa/MATα heterozygous (2 out of 16) isolates in both the subspecies, but no mating was observed under various laboratory conditions. One possible explanation was the incorrect maturation of the transcripts of MTL1 and MTL2 regulatory proteins (Sai *et al.*, 2011). Further evidence of mating was found a few years later with a comparative analysis of two *C. orthopsilosis* isolates (Riccombeni *et al.*, 2012; Pryszcz *et al.*, 2014). Surprisingly the newly sequenced MCO456 (ATCC96141) Type 1 (isolated in Texas, USA) strain showed a high degree of heterozygosity, as heterozygous sites affected 17% of the genome compared to only 0.1% in the reference 90–125 Type 2 strain (Tavanti *et al.*, 2005; Pryszcz *et al.*, 2014). *In silico* data revealed a mixed genome as rDNA cluster came from a close relative of Type 2 strain, the ITS region and MTL locus possibly derived from a Type 1 ancestor, suggesting that it is most likely that MCO456 Type 1 strain is a consequence of mating between two parental lineages (Pryszcz *et al.*, 2014). The minor (0.3%) divergence found between mitochondrial genomes of the subspecies also supports the mating hypothesis, as mitochondrion inheritance was found to be uniparental in *Candida* species (Ni *et al.*, 2011). Besides MCO456, another Type 1 isolate, AY2 (isolated in Singapore) was also investigated (Chan *et al.*, 2011). Interestingly there was over 99.9% identity found between the two Type 1 hybrids. This phenomenon that strains isolated from very distant geographic regions (Texas, USA and Singapore) share almost the same genome, point to the fact that the hybrid might have formed once, obtained evolutionary advantage in virulence and might have spread worldwide. However, this hypothesis had two weak points: (1) the sample number was limited, and (2) no homozygous Type 1 strain was involved in the analysis (Pryszcz *et al.*, 2014). This gap was filled in 2016, when a large scale comprehensive analysis of *C. orthopsilosis* isolates was performed involving 27 newly sequenced strains deriving from all over the world and associated with human infection. Among them only one isolate was found to be homozygous (like strain 90–125), whereas all the others were heterozygous. Phylogenetic reconstruction based on the SNP distribution in heterozygous regions clustered the isolates into four distinct groups. This indicates that hybridization in the *C. orthopsilosis* species is not a unique event, but occurred at least four times. A similar approach revealed that all the investigated isolates derived from hybridization events between the same parental lineages. To unify the nomenclature of the parental strains it was suggested to use “Parent A” and “Parent B” instead of “Type 1” and “Type 2”. “Parent A” homozygous strain is equal to Type 2 isolate represented by 90–125. “Parent B” is a hypothetical strain that has not yet been identified. “Parent A” and “Parent B” are 5% different in genome sequence, and they possibly went through hybridization and formed “Type 1” hybrids. Upon hybridization the tetraploid state can be resolved by random chromosome loss resulting in a (nearly) diploid genome, which is a known process in *C. albicans* (Bennett and Johnson, 2003). It is likely that similar events could have happened to *C. orthopsilosis* hybrids, but the involvement of sexual processes can not be completely excluded (Schroder *et al.*, 2016).

Candida metapsilosis – The Virulent Hybrid

C. metapsilosis is the third member of the species complex and is least frequently associated with clinical disease (Gomez-Lopez *et al.*, 2008; Silva *et al.*, 2009a; Canton *et al.*, 2011; Feng *et al.*, 2012). Perhaps this was the reason why its genome was a missing link right until 2015, when the comparative analysis of the genome of eleven clinical isolate was published (Pryszcz *et al.*, 2015). Nearly 6000 protein-coding genes were identified in the 13.3 Mb genome. The results, similarly to *C. orthopsilosis*, revealed hybridization between two parental strains, being approximately 4.5% divergent in sequence. Molecular evidence suggests that all 11 strains involved in the analysis are derivatives of the same hybrid. However, as with *C. orthopsilosis*, it is not clear whether sexual processes were involved in the hybridization event. Although no MTL genes had previously been found in 18 *C. metapsilosis* isolates by PCR, whole genome sequencing revealed strains carrying at least portions of both mating type loci; therefore, mating

can be considered as a possible mechanism for hybrid formation (Sai *et al.*, 2011; Prysacz *et al.*, 2015). The fraction of the heterozygous regions varied between 54.5%–61.3% and 63.4%–68.5% across strains depending on the parameters used for *in silico* analysis, meaning that either the hybridization event is very recent or this heterozygous state is stable and loss of heterozygosity occurs slowly. Moreover, 84 deletions and 87 duplications were identified among the samples in question. This is in agreement with the results of Hensgens and colleagues who found *C. metapsilosis* species to be highly heterogeneous using AFLP genotyping (Hensgens *et al.*, 2009). Since all eleven *C. metapsilosis* isolates derived from clinical sources and they most likely represent descendents of the same hybrid, one might consider that by this process a new species emerged that was capable of adapting to human host and eventually acting as a pathogen under given circumstances (Prysacz *et al.*, 2015). This hypothesis would have been supported further if the parental isolates were available, but unfortunately no such strains have yet been found. It is also not known if the parental strains are pathogenic or even still exist in the first place.

Candida parapsilosis Sensu Lato – Genetic Manipulation

The first genetically altered mutant of the complex was created in 2002. It was a galactokinase auxotroph strain of *C. parapsilosis* complemented with the functional allele of the gene cloned into a circular plasmid (Nosek *et al.*, 2002a). Since then, many homozygous deletion mutants were generated in *C. parapsilosis sensu stricto* according to the methods developed and improved during the last 15 years (Gacser *et al.*, 2005; Ding and Butler, 2007; Gacser *et al.*, 2007; Holland *et al.*, 2014). Efficient genetic manipulation requires three parameters optimized: (1) a selectable marker, (2) a target locus, (3) a method for transformation.

Selectable markers represent a class of reporter genes, as they “report” if they (and most likely the construct they are the part of) are in the cell or not. The ones used in *C. parapsilosis sensu lato* can be divided into two groups: dominant selectable markers and auxotrophy markers. The huge advantage of dominant selectable markers is that they can be used in prototroph strains (i.e., in practically any isolates). The first attempt of using such a system in *C. parapsilosis sensu stricto* was in 2005. Gacser and colleagues adopted a technique used in *C. albicans* that consisted of a drug called mycophenolic acid that can be neutralized by the enzyme inosine monophosphate dehydrogenase 3. The gene is encoded in *C. albicans*, and must be artificially overexpressed to take effect against the chemical (Kohler *et al.*, 1997; Gacser *et al.*, 2005). The major problem with dominant markers is that since *C. parapsilosis sensu lato* species are diploid, to delete both alleles of a given gene, two rounds of transformation have to be performed. But once the heterozygote is resistant to a given drug, how can one use the same drug again to create the homozygote? To resolve the problem, a system was developed that used a so-called recyclable selection marker. In *C. albicans*, the auxotrophy marker *URA3* is subsequently replaced with a dominant marker (nourseothricin acetyl transferase). The construct carrying the marker gene is flanked by two recognition sites of a site specific recombinase called flippase that upon activation removes all the sequences between the recognition sites, including the flippase, its promoter and most importantly the marker gene; therefore, the same cassette can be used again to remove the second allele (Kilby *et al.*, 1993; Morschhauser *et al.*, 1999; Staib *et al.*, 1999; Shen *et al.*, 2005). This technique was adopted by two different groups and used to perform the first targeted gene deletions in *C. parapsilosis sensu stricto* (Ding and Butler, 2007; Gacser *et al.*, 2007). Besides dominant selectable markers, auxotrophy markers are also possible to use. The drawback of this approach is the need of an auxotroph strain. Obviously if one decides to delete the same region in different prototroph isolates, this system is not usable. Pioneering work was done by Nosek and coworkers, who created the first auxotrophy selection system in *C. parapsilosis sensu stricto* utilizing a galactose auxotroph recipient strain and the galactokinase gene of *C. parapsilosis sensu stricto* isolated and cloned into a plasmid (Nosek *et al.*, 2002a). However to create knock out mutants (without the use of recyclable markers), the recipient strain must be a double auxotroph, which requires more work to create. But once the double auxotroph strain is available, the mutant generation is much more efficient than the recyclable technique in terms of time and effort. This method was elaborated by Noble and Johnson for *C. albicans* and used later by Holland and coworkers in *C. parapsilosis sensu stricto* to create large scale gene deletion libraries in these species (Noble and Johnson, 2005; Holland *et al.*, 2014).

Circular plasmids encoding an autonomously replicative sequence (ARS) can exist in *C. parapsilosis sensu stricto* (without integration into the genome), although they are not mitotically stable, meaning that without selection, they are eliminated rapidly (Nosek *et al.*, 2002a). Interestingly some circular constructs are stable without the ARS, while others are not. It is possible that the stable ones possess a region that can act as an “ARS-like” element (Nosek *et al.*, 2002a; Gacser *et al.*, 2005). In contrast to circular replicative elements, linear constructs (linearized plasmids or PCR products, etc.) tend to integrate by recombination into the genome and therefore be mitotically stable, which can be a targeted process or occur randomly. Randomly integrating constructs (or at least some of them) might have a special preference to dedicated regions of the genome, called hotspots (Gacser *et al.*, 2005). Targeted gene deletion can be achieved by adding homologous sequences of the flanking regions of the targeted locus in question to the ends of the linear constructs used for transformation. This can be performed by classical molecular techniques (amplification of homolog flankings by PCR, digesting and ligating them around the marker construct) or by PCR-mediated fusion as reported recently (Gacser *et al.*, 2007; Holland *et al.*, 2014). In general approximately 150 base pairs were found to be efficient, but later 400–500 or even 700 base pair long homologous sequences were used (Ding and Butler, 2007; Gacser *et al.*, 2007; Horvath *et al.*, 2012; Holland *et al.*, 2014; Grozer *et al.*, 2015). Even though it is called targeted, ectopic integration (when the construct does not integrate into the target locus, but some other region) can occur.

Once the construct is ready for transformation a reliable method is needed to allocate the DNA into the cell. To do so three methods were adopted and optimized for transforming *C. parapsilosis sensu lato*: (1) Biolistics, (2) chemical transformation, and (3)

electroporation. Biolistics (often referred as “gene gun”) is a physical method that utilizes heavy metal (wolfram or gold) particles coated with the DNA construct that are accelerated by a rapid helium gas burst. The metal particles (and the DNA) reach a speed so great that they can hit through not only the membrane but also the cell wall of the yeast cells (Klein *et al.*, 1992). Although there is a publication of using biolistics to transform *C. parapsilosis sensu stricto* with replicative elements, it was not efficient and the procedure required special equipment (Zemanova *et al.*, 2004). Instead, chemical transformation and electroporation have become the standard everyday protocols to follow. Chemical transformation by the Lithium-acetate/single-strand DNA/polyethylene glycol method was the first approach successfully used to genetically modify *C. parapsilosis sensu stricto*. The advantage of the method is that it does not require a dedicated machine or equipment. This method yielded a transformation efficiency of 10^3 transformants μg^{-1} DNA using a non-integrative construct (Nosek *et al.*, 2002a). Although it was approximately ten times more efficient than biolistics it was still less than what had been achieved in other *Candida* species using electroporation (Zemanova *et al.*, 2004; Voronovsky *et al.*, 2002). The principles of electroporation were discussed by Shigekawa and Dower where the electroporator device applies a short direct current pulse that temporarily opens pores in the plasma membrane through of which DNA molecules can pass (Shigekawa and Dower, 1988). As the cell wall represents an additional barrier, it must be weakened by (Tris-(hydroxymethyl)-aminomethane Ethylene-diamine-tetraacetate) Tris-EDTA, Lithium-acetate and Dithiothreitol treatment. Combining these methods resulted in an increase of two orders of magnitude μg^{-1} DNA in the transformation efficiency compared to chemical transformation, leading to the general use of this approach (Zemanova *et al.*, 2004; Nguyen *et al.*, 2011; Horvath *et al.*, 2012; Grozer *et al.*, 2015). However, it was subsequently determined that the efficiency of the electroporation and chemical method is highly strain dependent. For example, *C. parapsilosis sensu stricto* SR23 and GA1 isolates are more effectively transformed by using electroporation, whereas CLIB 214 and its derivatives are more amenable to chemical transformation (Zemanova *et al.*, 2004; Horvath *et al.*, 2012; Holland *et al.*, 2014; Perez-Garcia *et al.* 2016).

Additionally, there is a study describing the first deletion mutant in *C. orthopsilosis*, which was generated using a recyclable nourseothricin selection marker that was introduced to the cells by electroporation to create *his1* and *leu2* homozygous deletion strains to screen possible mating events (Sai *et al.*, 2011). In contrast, no *C. metapsilosis* transformant has been reported to date.

Candida parapsilosis Sensu Lato – Virulence

Virulence is neither a property of a pathogen nor the host, rather it is a term that characterizes the outcome of the interaction between them. Virulence depends on the susceptibility of the host and properties related to the pathogen. These latter ones are called virulence factors, which, when altered, cause attenuated damage in a given system upon interaction (Casadevall and Pirofski, 1999). Cellular organisms developed protective mechanisms during evolution against obligate or opportunistic pathogens to maintain their own integrity. In higher eukaryotes the immune system is responsible for performing such tasks. It has humoral – (water soluble molecules, for example antibodies, complement proteins, defensins, etc.) and cellular components (phagocytes, B-cells, T-cells, etc.). It also can be divided to an ancient innate (monocytes, neutrophils, etc.) component and an evolutionary more recent adaptive branch (represented by B-cells and T-cells) (Batista and Harwood, 2009; Sarma and Ward, 2011; Ganz, 2003; Dale *et al.*, 2008; Crotty, 2015).

Candida cells are often associated with the skin and medical devices. In terms of pathogenesis, yeast cells have to overcome immune system defenses, most usually epithelial cells and phagocytes, to cause disease; therefore studies examining *C. parapsilosis sensu lato* virulence primarily focus on properties related to such interactions. Although overall tendency in virulence ranges from *C. parapsilosis sensu stricto* to *C. orthopsilosis* and *C. metapsilosis* in a decreasing order, the virulence attributes within species is a strain dependent characteristic (Sabino *et al.*, 2011; Nemeth *et al.*, 2013). Historically, the first attempt to gain insight into *C. parapsilosis sensu stricto* - host interaction *in vivo* was in 1962 by Andriole and Hasenclever, who investigated the survival of alloxan treated mice inoculated with different *Candida* species. They established that *C. parapsilosis sensu stricto* caused 40% mortality after one day of intravenous infection irrespectively of the alloxan treatment, and suggested the high dosage (10^8 yeast cells) as the most possible factor (Andriole and Hasenclever, 1962). This was proven a few years later by Goldstein and colleagues, who intravenously infected mice with lower inocula and monitored the animals for 21 days. They found that *C. parapsilosis sensu stricto* was cleared from all the organs examined (lung-heart, liver-spleen, kidneys, brain). However, clearance was significantly delayed when mice were treated with steroid (cortisone) (Goldstein *et al.*, 1965).

Morphology

C. parapsilosis sensu lato species typically grows as yeast-like cells, but *C. parapsilosis sensu stricto* and *C. orthopsilosis* strains are also able to form pseudohyphae (Nemeth *et al.*, 2013). The prefix “pseudo” is used because these filament-like structures are elongated, similar to true hyphae of *C. albicans*, but the two formations are fundamentally different. Pseudohyphae consist of mostly ellipsoid shaped cells that are attached to each other at the site of septation, while true hyphae are tube like structures with parallel sides without obvious constrictions between the cells and the first septum is located in the tube-like structure distant from the mother cell (reviewed in Berman and Sudbery, 2002). Filamentation can be induced by growing *C. parapsilosis sensu lato* species in the presence of 5% (V/V) CO_2 or in fetal bovine serum (FBS) containing media (Sabino *et al.*, 2011; Nemeth *et al.*, 2013). Different cell morphologies can affect colony morphology and biofilm forming abilities as well (discussed subsequently) (Laffey and Butler,

2005). Although the pseudohypha forming capabilities of the *C. parapsilosis sensu lato* species is poorly studied, it appears that in contrast to *C. parapsilosis sensu stricto* and *C. orthopsilosis*, *C. metapsilosis* is unable to form pseudohyphae. However, among *C. parapsilosis sensu stricto* and *C. orthopsilosis* isolates both pseudohypha producers and non-producers have been identified (Sabino *et al.*, 2011; Nemeth *et al.*, 2013; Gago *et al.*, 2014). Interestingly significantly larger proportion of *C. parapsilosis sensu stricto* strains cultivated from blood cultures formed filaments than environmental isolates (Sabino *et al.*, 2011). Pseudohypha formation might be important in host - pathogen interactions since pseudohypha-positive *C. orthopsilosis* isolates are less efficiently killed by J774.2 murine macrophages compared to pseudohypha negative cells. Additionally, this observation is also the case when the producer and non-producer strains of the species group are compared (Nemeth *et al.*, 2013).

Adherence and Biofilm Formation

C. parapsilosis sensu stricto has a strong predilection to adhere to medical devices, including implants, and the yeast has been frequently isolated from hands of healthcare workers, particularly in outbreak investigations (Ramage *et al.*, 2006; Bonassoli *et al.*, 2005). *C. parapsilosis sensu stricto* tends to form lower amounts and less compact biofilms than *C. albicans*. *C. albicans* biofilm on silicon elastomer is shallow and contains yeast-like, pseudohyphal – and hyphal elements embedded in a rich extracellular matrix (Andes *et al.*, 2004; Ramage *et al.*, 2004). In contrast, *C. parapsilosis sensu stricto* biofilms are thin and consists of yeast-like cells with a basal yeast layer but without significant extracellular matrix (Kuhn *et al.*, 2002). Interestingly biofilm forming capability of *C. parapsilosis sensu stricto* cells depends on their morphology. Different morphotypes correlate with distinct adhesion properties and varied colony morphologies (smooth, rough, snowball, crepe, crater and concentric) between which fungal cells can undergo a morphological “switch”, a process known as phenotypic switching. Morphology is not conserved among strains, but it can be changed and/or facilitated by adding specific chemicals (Lott *et al.*, 1993; Enger *et al.*, 2001; Laffey and Butler, 2005). In addition to morphology, adherence and biofilm formation among *Candida* species strongly depends on the medium, pH and oxygen tension (Hawser and Douglas, 1994; Ramage *et al.*, 2006; Silva *et al.*, 2009b). Although biofilms are formed by the different *C. parapsilosis sensu lato* species, there is significant variability in their biofilm forming capabilities. *C. orthopsilosis* and *C. parapsilosis sensu stricto* biofilms on silicon elastomer material are similar in terms of dry weight in mature biofilms (48 h), but in contrast to *C. orthopsilosis*, *C. parapsilosis sensu stricto* tends to have a solid lag phase, while *C. orthopsilosis* biofilms form rapidly. In contrast, *C. metapsilosis* forms less biofilm (Lattif *et al.*, 2010). Similarly, *C. parapsilosis sensu stricto* and *C. orthopsilosis* are more adherent and form more biofilm *in vitro* (with human buccal epithelial) and *in vivo* (in experimental mouse vaginal candidiasis model) compared to *C. metapsilosis* (Bertini *et al.*, 2013). However, the overall adherent properties of *C. parapsilosis sensu stricto* are weak or moderate compared that to those of *C. albicans* in vascular endothelium and human epithelial models (Klotz *et al.*, 1983; Bendel *et al.*, 1995). Notably, the factors involved in *C. parapsilosis sensu stricto* adherence are poorly understood. Agglutinin-like sequences (Als) are glycosylphosphatidylinositol (GPI) anchored cell surface proteins responsible for adhesion, and they compose a large and well characterized family in *C. albicans*, and Als3 is one of the best characterized adhesin (Hoyer, 2001; Phan *et al.*, 2007; Hoyer *et al.*, 2008; Hoyer and Cota, 2016). A recent study reported the involvement of the *C. albicans* ALS3 ortholog gene CPAR2_404800 in *C. parapsilosis sensu stricto* adhesion. The homozygous mutant lacking CPAR2_404800 was attenuated in its ability to adhere to buccal epithelial cells *in vitro* and to bladder epithelium in a murine urinary tract infection model compared to wild-type (Bertini *et al.*, 2016). Additionally, the regulation of biofilm formation in *C. parapsilosis sensu stricto* is still unclear. However, the ortholog of *C. albicans* BCR1 gene (a regulator of biofilm formation) in *C. parapsilosis sensu stricto* (CpBCR1) encodes a transcription factor that is required for adhesion and biofilm formation on silicone surface. In *C. albicans* Bcr1 is a positive regulator of HWP1 that encodes a GPI-anchored protein responsible for adhesion to buccal epithelial cells (Staab *et al.*, 1999; Nobile and Mitchell, 2005; Nobile *et al.*, 2006b; Mayer *et al.*, 2013). Although *C. parapsilosis sensu stricto* lacks the ortholog of HWP1, it encodes one of its close relatives, CpRBT1, and this gene has been found to be under the regulation of CpBcr1 (Braun *et al.*, 2000; Ding and Butler, 2007). Interestingly, while in *C. albicans* Bcr1 promotes the expression of ALS1 and ALS3 in addition to HWP1, CpBcr1 appears to promote CpRBT1, but not the CpALS genes (Nobile *et al.*, 2006a; Ding and Butler, 2007). This suggests that the induction of ALS3 genes in the two pathogens occurs through different regulatory pathways.

Secreted Enzymes

Secreted enzymes play vital roles in nutrition acquisition in nature and during interaction with the host. Indeed, the host environment is limited in accessible carbon and nitrogen sources. To digest such macromolecules, *Candida* species secrete proteinases, lipases and phospholipases. The production of phospholipase in *C. parapsilosis sensu stricto* is strain dependent and their involvement in virulence remains in question (Mohan das and Ballal, 2008; Pakshir *et al.*, 2013; Ramos Lde *et al.*, 2015; Shirkhani *et al.*, 2016). However, proteinases and lipases are well characterized and linked to virulence. Genes of these proteins expanded and compose gene families in certain pathogenic species that have resulted in the divergence of the enzymes in terms of substrate specificity, inducibility and expression pattern (Monod *et al.*, 1994; Hube *et al.*, 2000; Naglik *et al.*, 2004; Schaller *et al.*, 2005).

Genomic analysis of the *C. parapsilosis sensu lato* species complex revealed a remarkable expansion of secreted aspartyl proteinase (in *parapsilosis*) (SAPP) genes. While in *C. orthopsilosis* 11 such ORF were identified, the genome of *C. metapsilosis* and *C. parapsilosis sensu stricto* encode 14 potential SAPPs (Pryszcz *et al.*, 2015). The ability of *C. parapsilosis sensu stricto* to secrete proteinases and their association with virulence was already established in the 1980s (Macdonald, 1984; Ruchel, 1984; Ruchel

et al., 1986). By the 1990s, secreted proteinases were shown to degrade secretory Immunoglobulin A, and isolates from patients with *C. parapsilosis sensu stricto* vulvovaginitis were found to secrete significantly higher amount of proteinases than isolates from asymptomatic carriers (Douglas, 1988; Agatensi *et al.*, 1991). Although proteinase secretion is a general property of *C. parapsilosis sensu stricto*, examinations of *C. metapsilosis* and *C. orthopsilosis* have revealed both producers and non-producers (Sabino *et al.*, 2011; Nemeth *et al.*, 2013; Gago *et al.*, 2014). In *C. parapsilosis sensu stricto* SAPP1 and SAPP2 have been investigated in detail. The proteins encoded by these genes differ in their substrate specificity, enzymatic activity and expression patterns (Merkerova *et al.*, 2006; Hruskova-Heidingsfeldova *et al.*, 2009). SAPP1 is duplicated, the paralogs are distinguished as SAPP1a and SAPP1b, and they are similar in nucleotide sequence, except only one nucleotide that however, does not alter the protein sequence (Horvath *et al.*, 2012). The mature protein localizes to the cell wall, and it is expressed only when exogenous protein is present as the sole nitrogen source in the media (Vinterova *et al.*, 2011; Hruskova-Heidingsfeldova *et al.*, 2009). The disruption of the alleles of SAPP1a and SAPP1b (Δ/Δ sapp1) in *C. parapsilosis sensu stricto* increased the resulting mutant's susceptibility to human serum and reduced its resistant to primary human phagocytes (peripheral blood mononuclear cells (PBMCs) and PBMC-derived macrophages (PBMC-DM)) in terms of phagocytosis and killing compared to wild-type yeasts (Horvath *et al.*, 2012). The expression of SAPP2 appears to be constitutive, as it has been detected in every media examined, but the expression is significantly increased in the Δ/Δ sapp1 mutant compared to wild-type (Hruskova-Heidingsfeldova *et al.*, 2009; Horvath *et al.*, 2012).

Based on computational predictions, lipases represent another major secreted family of pathogenic *Candida* species. In *C. albicans* there are 10 lipase genes identified to date, and some of them have been associated with virulence (Hube *et al.*, 2000; Stehr *et al.*, 2004; Schofield *et al.*, 2005). *C. parapsilosis sensu stricto* have been biochemically studied since the 1990s, and more recent studies have examined their potential utilization for biotechnological purposes (Briand *et al.*, 1995; Vaysse *et al.*, 1997; Neugnot *et al.*, 2002; Rodrigues *et al.*, 2016; Kannoju *et al.*, 2017). In the *C. parapsilosis sensu lato* group, the predicted numbers of lipase genes are 4 (*C. parapsilosis sensu stricto* and *C. orthopsilosis*) and 5 (in *C. metapsilosis*) (Pryszcz *et al.*, 2015). The higher number of lipase genes in *C. metapsilosis* is in contrast to laboratory observations, as no lipase producer *C. metapsilosis* strain has yet been identified, suggesting that the predicted genes are not functional (Nemeth *et al.*, 2013). However, it is possible that the induction media were not specifically optimized for *C. metapsilosis*. *C. parapsilosis sensu stricto* and *C. orthopsilosis* have both lipase positive and negative isolates. Notably, *C. parapsilosis sensu stricto* and *C. orthopsilosis* lipase producer strains are able to cause significantly more damage to J774.2 macrophages *in vitro* than non-producer ones (Nemeth *et al.*, 2013). Targeted removal of *Candida parapsilosis sensu stricto* lipase genes (*CpLIP*) *CpLIP1* and *CpLIP2* demonstrated their role in nutrient acquisition and virulence. Although both genes were removed, reintroduction of only one allele of wild-type *CpLIP2* totally complemented both the examined phenotypes, suggesting that *CpLIP1* (and other predicted lipase genes) might not be actively transcribed or proteolytically active under specific circumstances (Neugnot *et al.*, 2002). In the Δ/Δ cplip1-cplip2 mutant the overall lipase production was abolished (suggesting that other predicted lipases might not be expressed) and an apparent growth deficiency in mediums containing fatty acids as a sole carbon source was observed. Moreover *CpLip2* is also involved in biofilm formation on polyethylene, silicon and polystyrene surfaces and, more importantly, in virulence both *in vitro* and *in vivo*. The null-mutant was less resistant to phagocytosis and killing by murine macrophages, mature and immature human PBMC derived dendritic cells and PBMC-DM *in vitro*, and in a peritoneal mouse and a rat neonate model (Gacser *et al.*, 2007; Nagy *et al.*, 2011; Toth *et al.*, 2014a; Trofa *et al.*, 2011). Moreover, the phagocytes responded with higher chemokine and inflammatory cytokine expression on RNA and protein levels in *in vitro* interactions (Nagy *et al.*, 2011; Toth *et al.*, 2014a). The possible reason of the more efficient uptake was investigated by Toth and colleagues, who found an increase in macrophage (J774.2) migration towards lipase null-mutant fungal cells compared that to the wild-type yeasts (Toth *et al.*, 2015). In another *in vitro* system utilizing PBMC-DMs, the Δ/Δ cplip1-cplip2 strain avoided phagosome - lysosome fusion (and consequently macrophage killing) less effectively than wild-type cells, and induced a significantly higher expression and secretion of TNF α , IL-1 β , and IL-6 inflammatory cytokines (Toth *et al.*, 2014a). These findings indicate that secreted lipases might be the tools *C. parapsilosis sensu stricto* utilizes to attenuate host inflammatory responses.

Host Interaction

Recognition of pathogens upon interaction occurs between so-called pathogen associated molecular patterns (PAMP) and the receptors of the host cells called pattern recognition receptors (PRR). PAMPs are evolutionary conserved molecules that are indispensable components of a given pathogen (i.e., double stranded RNA of certain viruses, lipopolysaccharide of bacteria, β -glucan components of the fungal cell wall, etc.). PRRs are germ-line encoded receptors that can bind one or a few types of PAMPs, which triggers a cell response leading to phagocytosis and/or secretion of cytokines and other soluble factors. Such soluble factors are, for example, small molecular weight defensins, which are secreted primarily by neutrophils (α -defensins) and epithelial cells (β -defensins). Defensins are positively charged, cysteine rich proteins, often acting as pore-forming agents (reviewed in Ganz, 2003; Lehrer and Lu, 2012). *C. parapsilosis sensu stricto* induces significant release of α -defensins from primary human neutrophils and interactions with a human intestinal cell line, Caco-2, leads to an increased expression and secretion of human β -defensin 2 (HBD-2), although the difference compared to the non-infected Caco-2 controls was not significant (Gacser *et al.*, 2014).

In addition to the secretion of biologically active molecules, phagocytosis of pathogens and intracellular killing are effective mechanisms for eradicating invading microbes. After engulfment, a pathogen can be eliminated through various mechanisms including reactive chemical compounds, enzymatic digestion, ion chelators (Babior *et al.*, 2002; Aratani *et al.*, 1999; Vazquez-Torres *et al.*, 1996; Samaranayake *et al.*, 2001; Nikawa *et al.*, 1993). The first step of host-pathogen interaction is the recognition of

the microbe by the host effector cell. Successful pathogens have evolved numerous, specific paths to avoid the interaction between their PAMPs and the PRRs of the host. Although the involvement of *C. albicans* cellular components on host interactions has been intensively studied, our knowledge on such components of *C. parapsilosis sensu lato* remains limited (Ruiz-Herrera *et al.*, 2006; Chaffin, 2008; McKenzie *et al.*, 2010). *C. parapsilosis sensu stricto* cells are ingested and efficiently killed by J774.2 murine macrophages *in vitro*, and, during the interaction, the phagocytes respond with the transcription of inflammatory cytokines (IL-1 β and TNF α) (Nemeth *et al.*, 2014). In terms of the components, the cell walls of the *C. parapsilosis sensu lato* species appear to be molecularly similar to the ones present in *C. albicans*, but their proportions and, consequently, the overall structures are diverse. Interestingly the cell wall porosity levels of the species complex is approximately twice as much as that of *C. albicans*, which is due to the shorter mannan chains attached to cell wall proteins in the *C. parapsilosis sensu lato* species (Shibata *et al.*, 1995; Estrada-Mata *et al.*, 2015). In line with this, the *C. parapsilosis sensu lato* species possess more glucan underneath a mannan layer, possibly as a result of a known compensatory mechanism to maintain cell wall strength (Estrada-Mata *et al.*, 2015; Walker *et al.*, 2013). The PRRs involved in the recognition and subsequent cytokine secretion playing role in *C. parapsilosis sensu lato* - phagocytes interaction are the C-type lectins Dectin-1 and mannose receptor (MR), which recognize β -1,3 glucan and N-linked mannans respectively, and toll-like receptor 4 (TLR4), binds O-linked mannans (Brown and Gordon, 2001; Medzhitov *et al.*, 1997; Tada *et al.*, 2002; Garner *et al.*, 1994; Yamamoto *et al.*, 1997; Netea *et al.*, 2006). All of these receptors are involved in TNF α secretion, while IL-1 β production was found to be MR and Dectin-1 dependent. However, the involvement of TLR4 in IL-1 β secretion might be a strain specific property since some reports describe TLR4 and Dectin-1 dependent IL-1 β production (Toth *et al.*, 2013; Estrada-Mata *et al.*, 2015; Perez-Garcia *et al.*, 2016). Indeed the involvement of receptors in cytokine secretion induced by different isolates of the same species is a known phenomenon in *C. albicans* - host interactions (Marakalala *et al.*, 2013; Netea *et al.*, 2010). The lack of N-linked mannans in the outer layer leads to increased secretion of IL-1 β , TNF α , IL-10 (anti inflammatory cytokine) and IL-6 from human PBMCs, and this compound is not necessary to efficient phagocytosis. Notably, *C. orthopsilosis* differed from the other two members of the group in terms of decreased TLR4 dependent IL-6 and MR dependent IL-10 secretion, which is consistent with the observation of the highly exposed glucan and chitin content of *C. orthopsilosis* compared to *C. parapsilosis sensu stricto* and *C. metapsilosis* (Estrada-Mata *et al.*, 2015).

C. parapsilosis sensu stricto and *C. albicans* induce the differentiation of distinct T-helper subpopulations. In contrast to PBMCs secreting increased amounts of Th1 and Th17 cytokines (IFN γ , IL-1 β and IL-17, IL-22 respectively) upon challenge with *C. albicans*, interactions with *C. parapsilosis sensu stricto* induces the release of IL-10, a typical Th2 cytokine. Although the investigation of the T-helper response to *C. parapsilosis sensu stricto* is a very new field, recent work demonstrates that *C. parapsilosis sensu stricto* is able to switch the Th1/Th17 - Th2 bias towards the latter with a yet unknown mechanism to avoid the antifungal activity induced by Th1/Th17 cytokines (Toth *et al.*, 2013). Moreover, Galectin-3, another lectin type receptor that can be both anchored onto the cell surface and secreted, is involved with *C. parapsilosis sensu stricto* recognition in a systemic mouse infection model, as the fungal burden and the damage in the kidney of Galectin-3 knock-out mutants were higher compared to the ones of the wild-type mice. Interestingly, this study also found that the level of Galectin-3 in the sera of human neonates was significantly lower than in the samples of adults, which could be a possible explanation for why newborns are more susceptible to *C. parapsilosis sensu stricto* infection than adults (Linden *et al.*, 2013).

Successful pathogens utilize mechanisms by which they can avoid elimination by host mechanisms. It has already been established that *C. parapsilosis sensu stricto* is capable of replicating, forming pseudohyphae, aborting host cell mitosis and inducing exocytosis, therefore escaping from phagocytes and endothelial cells (Toth *et al.*, 2014b; Glass *et al.*, 2015). Additionally, endothelial cells might act as fungal reservoirs during infection. *C. parapsilosis sensu stricto* can be uptaken by these cells, and once internalized they can be hidden away from patrolling neutrophil granulocytes (Glass *et al.*, 2015). As shown above, *C. parapsilosis sensu stricto* secreted lipases are able to attenuate PBMC derived dendritic cell and PBMC-DM cytokine secretion, phagosome - lysosome fusion and affect phagocyte migration (Nagy *et al.*, 2011; Toth *et al.*, 2014a). Moreover, lipases might further modulate the immune response, such as through altering the prostaglandin profile of the host (Toth *et al.*). Phospholipases can cleave membrane bound lipids resulting in the release of arachidonic acid, which can be processed further by the host to synthesize prostaglandins that can have either pro- or anti-inflammatory effects (Funk, 2001; Harris *et al.*, 2002). *C. parapsilosis sensu stricto* can produce prostaglandin E2 (PGE2), which is known to mediate T-cell response by promoting a Th2-type differentiation that, as mentioned earlier, is a poorly effective response to *Candida* (Grozer *et al.*, 2015; Harris *et al.*, 2002). In fact, *C. parapsilosis sensu stricto* induces human PBMC-DMs to produce more IL-10 and less IL-1 β , IFN γ , IL-17 and IL-22 compared to PBMC-DMs challenged with *C. albicans* (Toth *et al.*, 2013). In contrast to *C. albicans*, removal of the gene *OLE2* (putative $\Delta 9$ fatty acid desaturase) from the genome of *C. parapsilosis sensu stricto* did not decrease PGE2 production. However, the *de novo* fatty acid biosynthesis changed, as demonstrated by an increase in palmitoleic acid and oleic acid, and the mutant was less resistant to human PBMC-DMs. Moreover it induced higher IL-10 (Th2 cytokine) secretion than the wild-type (Grozer *et al.*, 2015). Changes in the fatty acid synthesis can also lead to an impaired capacity to form biofilms on polystyrene and silicone surfaces as well as a decreased resistance against macrophage killing (Nguyen *et al.*, 2009). The involvement of fungal fatty acid synthesis in virulence is also elucidated by the fact that *OLE1* (a fatty acid desaturase) is responsible for maintaining cell membrane integrity and invasive growth of *C. parapsilosis sensu stricto*, as an *OLE1* mutant was less resistant to human serum and phagocytosis *in vitro* and showed attenuated virulence in intravenous mouse infection model (Nguyen *et al.*, 2011). The interactions of *C. metapsilosis* and *C. orthopsilosis* with host cells are poorly studied. However, *C. metapsilosis* is significantly less resistant to host effector cells compared to *C. parapsilosis sensu stricto* and *C. orthopsilosis* (Orsi *et al.*, 2010; Sabino *et al.*, 2011; Nemeth *et al.*, 2013), which is in line with the limited clinical cases of disease due to *C. metapsilosis*. Interestingly, BV-2 mouse microglial cells challenged with *C. metapsilosis*

effectively formed phagosomes containing the yeast cells, whereas *C. parapsilosis sensu stricto* partially inhibited this process (Orsi *et al.*, 2010). Studies in a Greater wax moth (*Galleria mellonella*) larvae survival model further demonstrated that *C. metapsilosis* is significantly less virulent compared to the other members of the *sensu lato* species and *C. metapsilosis* was also more effectively phagocytosed by *Galleria mellonella* haemocytes compared to the other two members of the complex (Nemeth *et al.*, 2013; Gago *et al.*, 2014).

Introduction

Candida auris is a novel and multidrug-resistant *Candida* species first reported in Japan in 2009 (Satoh *et al.*, 2009) and since then has been reported in 35 countries in five continents. This emerging yeast that can cause invasive infections and spread easily in healthcare settings is associated with high mortality. *C. auris* has some properties that make it very different from other species of *Candida*: (1) It is hard to identify using conventional phenotypic techniques and is commonly misidentified in clinical laboratories (Jeffery-Smith *et al.*, 2018); (2) Pathogenic isolates of *C. auris* have emerged independently in three continents simultaneously (Lockhart *et al.*, 2017b); (3) *C. auris* is very resistant to antifungals displaying distinct mechanisms of antifungal resistance and some strains have demonstrated high minimum inhibitory concentrations (MICs) to all three major classes of antifungal agents, extreme multidrug-resistance (XMDR), a feature not seen before in other *Candida* species (Forsberg *et al.*, 2019); and (4) *C. auris* persists for weeks in healthcare environments, can colonize patients perhaps indefinitely and is easily transmitted among patients causing healthcare-associated outbreaks, mainly in critically ill patients (Ruiz-Gaitán *et al.*, 2018a).

All these attributes make *C. auris* a “superbug” concerning microbiologists, clinicians, hospital epidemiologists and health authorities. In June 2016 the Centers for Diseases Control and Prevention (CDC) released clinical alert to healthcare facilities and provided guidelines to clinical management, laboratory diagnosis and infection control. Likewise, European Center for Disease Prevention and Control, World Health Organization, Pan American Health Organization, Public Health England, Spanish Ministry of Health, and South African National Institute of Communicable Diseases also issued similar epidemiological alerts in 2016.

The sudden and simultaneous appearance of *C. auris* throughout the world, as a human-infecting pathogen, remains a mystery to scientists. A recently published study suggests that the global transformation of *C. auris*, possibly a former plant saprophyte, into a deadly pathogen may be due to global warming, which could have forced *C. auris* around the world to adapt to higher temperatures, making it easier to infect humans with the helpful avian flora acting as intermediary hosts (Casadevall *et al.*, 2019).

Therefore, proper prevention and control of *C. auris* in healthcare facilities requires better knowledge of this new yeast, rapid detection and accurate methods of surveillance and identification, appropriate treatment and outcome monitoring of infected patients, infection control strategies adapted to this new species, and a coordinated public health response.

Microbiological Characteristics

Biology and Morphology

Phylogenetic

C. auris is closely related to *Candida haemulonii*, *Candida pseudohaemulonii*, *Candida duobushaemulonii*, and *Candida heveicola* in the Metschnikowaceae clade of *Candida* genus (Satoh *et al.*, 2009; Daniel *et al.*, 2014). Phenotypically, based on traditional biochemical methods only, these species are very similar and could be hard to correctly distinguish one species from the others of this complex (Kathuria *et al.*, 2015).

Colony morphology

C. auris can grow in different culture media. On chromogenic media (CHROMAagar *Candida* or CAN2) it develops pale purple to pink colonies; on Sabouraud dextrose agar, *C. auris* forms dull white to cream, smooth colonies, and on malt extract agar, it grows as butyrous, white-gray, smooth colonies (Lone and Ahmad, 2019). *C. auris* has high tolerance for heat and salinity (can grow at temperatures up to 42°C and in media contained 10% NaCl) but does not grow in presence of 0.01% cycloheximide (Jeffery-Smith *et al.*, 2018). These characteristics can be used in the presumptive identification of this pathogen from other species.

Cellular morphology

Microscopically, *C. auris* cells are oval or elongated and appears in single, pairs or in aggregates. The size (2–3 × 2.5–5 µm) and growth rate is comparable to *Candida glabrata* than to *Candida albicans* and unlike other *Candida* species, *C. auris* does not form hyphae, pseudohyphae, germ tube or chlamydospore on cornmeal agar (Satoh *et al.*, 2009). However, occasional rudimentary pseudohyphae formation has been found in *C. auris*, either in vitro or in vivo *Galleria mellonella* model, suggesting it could be a strain dependent condition (Borman *et al.*, 2016). The presence of at least two cellular morphologies of *C. auris* (aggregating and nonaggregating cells) has been reported (Borman *et al.*, 2016; Ben-Ami *et al.*, 2017; Sherry *et al.*, 2017). Aggregating *C. auris* isolates are produced by the inability of daughter cells to separate after budding and cannot be disrupted by mechanical action and/or detergents. Interestingly, in *G. mellonella* infection model studies, the nonaggregating isolates demonstrated greater pathogenicity

than aggregating isolates (Borman *et al.*, 2016; Sherry *et al.*, 2017). Recently, a novel phenotypic switching system in *C. auris* has been reported which transits cells in three different cell types: typical yeast, filamentation-competent yeast and filamentous cells (Zhang and Hu, 2018). The heritable switch between the typical yeast and the filamentation-competent/filamentous phenotype is triggered by passage through a mammalian body, whereas the switch between the filamentation-competent and filamentous phenotype is nonheritable and is favored by low temperatures.

Biochemical features

The utilization of nitrogen and carbon sources by *C. auris* are distinct from other species of *Candida*. *C. auris* ferments glucose, trehalose (weak), sucrose (weak), but does not ferment maltose, lactose, galactose or raffinose. It assimilates glucose, maltose, D-trehalose, sucrose, D-melezitose, D-raffinase, soluble starch, galactitol, D-mannitol, citrate, sorbitol and Nacetyl-D-glucosamine (some strains) for carbon source. *C. auris* uses ammonium sulfate, cadaverine and L-lysine as nitrogen sources, but does not utilize sodium nitrate, potassium nitrate and ethylamine (Sato *et al.*, 2009; Anil Kumar *et al.*, 2014; Prakash *et al.*, 2016).

Virulence

In *G. mellonella* and murine models, *C. auris* presents similar or slightly less virulence as *C. albicans*, *C. glabrata* and *Candida tropicalis* but greater virulence than *C. haemulonii* (Borman *et al.*, 2016; Ben-Ami *et al.*, 2017; Fakhim *et al.*, 2018). Most *C. auris* strains form biofilms to different degrees while some do not form biofilms at all (Chatterjee *et al.*, 2015; Oh *et al.*, 2011). Biofilm formation has been demonstrated with non-aggregate forming strains and, to a lesser degree, aggregate-forming strains of *C. auris*; these biofilms are thin and composed mainly of yeast cells with very limited extracellular matrix (Larkin *et al.*, 2017; Sherry *et al.*, 2017). Notably, *C. auris* biofilms had less biomass when compared with those of *C. albicans* but greater biomass than those of *C. glabrata*. The capacity of *C. auris* to produce/secrete other virulence factors as phospholipase, proteinase, hemolysins, aspartic proteases and the presence of oligopeptide transporters and mannosyl transferases is strain-dependent, at different degrees, and lower than *C. albicans* (Kumar *et al.*, 2015; Chatterjee *et al.*, 2015; Larkin *et al.*, 2017; Sherry *et al.*, 2017).

Identification

C. auris can be misidentified by the commercially available biochemical-based yeast identification systems (API-20C AUX, VITEK-2 YST, BD-Phoenix, MicroScan and Auxacolor) used in clinical laboratories worldwide. Due to the lack of *C. auris* in their databases, these systems do not identify or, worse, misidentify *C. auris* with other species such as *Rhodotorula glutinis*, *Candida sake* or *Saccharomyces cerevisiae* (API-20C AUX), as *C. haemulonii* or *C. famata*, *C. lusitanae* or *C. famata* (VITEK-2YST VITEK), as *C. haemulonii* or *Candida catenulata* (BD-Phoenix), as *C. famata*, *C. lusitanae*, *C. guilliermondii*, *C. catenulata*, *C. albicans*, *C. tropicalis* or *C. parapsilosis* (MicroScan), and as *S. cerevisiae* (Auxacolor) (Lone and Ahmad, 2019; Jeffery-Smith *et al.*, 2018). To avoid the identification problems of commercial techniques, the use of CHROMagar *Candida* medium supplemented with Pal's agar has been suggested as a simple low-cost method to distinguish between *C. auris* and *C. haemulonii* isolates (Kumar *et al.*, 2017). In our own experience the CHROMagar *Candida* medium supplemented with fluconazole (32 mg/L), used as a primary culture medium, is very useful for presumptive identification of *C. auris* in colonization surveillance cultures (unpublished data).

Currently, molecular methods or matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) are recommended for definitive *C. auris* identification. Sequencing of genetic loci, including D1/D2, RPB1, RPB2, and internal transcribed spacer (ITS) domains of the rRNA, has proven useful in the identification of *C. auris* (Chowdhary *et al.*, 2013; Sharma *et al.*, 2015), but it is unlikely to be available outside reference laboratories. Bruker Biotyper and bioMérieux VITEK MS MALDI-TOF MS identification platforms, using their latest updated libraries, properly identify *C. auris* and are the most reliable methods to identify this species in the majority of clinical laboratories (Lockhart *et al.*, 2017a). For the typing of *C. auris* isolates, a range of molecular techniques, including AFLP analysis, pulsed-field gel electrophoresis, M13 DNA fingerprinting or sequencing of genetic loci in addition to MALDI-TOF MS have been successfully implemented (Schelenz *et al.*, 2015; Girard *et al.*, 2016; Sharma *et al.*, 2015). Besides, whole genome sequencing (WGS) is increasingly being used to identification and typing of *C. auris* cases (Chatterjee *et al.*, 2015; Lockhart *et al.*, 2017b; Tsay *et al.*, 2017; Pchelin *et al.*, 2019). This method provides a better epidemiological analysis than all other. However, it is more expensive and requires higher skill and data processing capacity.

Other rapid culture-independent diagnostic techniques are under development, including polymerase chain reaction (PCR) and real-time PCR tests. These techniques will enhance the capacity to screen patients and identify new cases colonized by *C. auris* allowing a rapid implementation of infection control measures (Kordalewska *et al.*, 2017; Martínez-Murcia *et al.*, 2018; Ruiz-Gaitán *et al.*, 2018b; Leach *et al.*, 2018).

Antifungal Resistance

At present, because there are no established clinical breakpoints for this new specie, the MICs obtained for *C. auris* isolates have been compared to the breakpoints determined for other *Candida* species by the CLSI and EUCAST reference methodologies (CLSI, 2018; EUCAST, 2018). For epidemiological purposes, the CDC also maintains the conservative breakpoints already in use for other *Candida* spp.: ≥ 32 mg/L for fluconazole, ≥ 2 mg/L for amphotericin B, ≥ 4 mg/L for anidulafungin and micafungin, and ≥ 2 mg/L for caspofungin; for voriconazole and other triazoles, fluconazole resistance may be considered as

Table 1 In vitro antifungal resistance of 1044 *C. auris* isolates (data from 14 different studies from 10 countries in four continents)

Drug (no. of isolates)	Average percentage of resistance or non-WT isolates (%)
Fluconazole (939)	73.92
Isavuconazole (851)	4.13
Itraconazole (334)	39.14
Posaconazole (811)	28.75
Voriconazole (974)	35.92
Anidulafungin (903)	23.20
Micafungin (956)	18.36
Amphotericin B (894)	19.00

surrogate marker (Tsay *et al.*, 2017). Applying these breakpoints resistance to fluconazole exceeds 90%, while resistance to voriconazole may approach 60% of all *C. auris* isolates. Resistance to amphotericin B has been reported in up to 35% of isolates, whereas resistance to echinocandins has been between 2%–8%. Overall, more than 40% isolates were resistant to two antifungal classes (multi drug-resistant -MDR-), and about 4% of isolates have been resistant to all the three major classes of anti-fungal drugs, which makes them extreme drug-resistant (XDR) isolates, this status has never been observed before in *Candida* species (Lockhart *et al.*, 2017b; Chowdhary *et al.*, 2018; Ruiz Gaitán *et al.*, 2019a). Low MICs for the newer triazoles, such as posaconazole and isavuconazole, suggest that these antifungals maybe effective against *C. auris*. Arendrup *et al.* have proposed tentative CLSI and EUCAST epidemiological cut-off values (ECVs) for *C. auris* (Arendrup *et al.*, 2018). In a recent study, we have applied these ECVs to 73 bloodstream *C. auris* strains isolated during the Spanish outbreak (Ruiz-Gaitán *et al.*, 2018a) and to published MIC data of 14 studies from around the world that included more than 10 isolates each (Ruiz Gaitán *et al.*, 2019a). A total of 1044 isolates of *C. auris* were analyzed and the results are summarized in Table 1.

Although drug resistance mechanisms in *C. auris* are not established yet, these could be similar to those observed in other resistant *Candida* species: upregulation of efflux pumps (mainly ABC-type efflux pump) and biofilm formation for azole resistance (Ben-Ami *et al.*, 2017; Chatterjee *et al.*, 2015; Healey *et al.*, 2018), and gene mutations and biofilm formation for both, echinocandins or amphotericin B resistance (Sherry *et al.*, 2017; Kordalewska *et al.*, 2018; Hou *et al.*, 2019; Escandón *et al.*, 2018).

Persistence on Hospital Environment

One of the alarming characteristics of *C. auris* is its ability to persist on both dry and moist surfaces, bedding materials, floors, sinks, chairs, tables and other healthcare surfaces around infected or colonized patients, including medical equipment such as electrocardiogram leads, blood pressure monitoring cuffs, infusion pumps, and ventilators (Biswal *et al.*, 2017; Piedrahita *et al.*, 2017; Schelenz *et al.*, 2016; Ruiz-Gaitán *et al.*, 2018a). It has been confirmed that *C. auris* can persist on dry plastic surfaces for at least 2 weeks on culture and 1 month when their esterase activity (viability) is measured with a solid-phase cytometer (Welsh *et al.*, 2017). Therefore *C. auris* may spread through contact with contaminated environmental surfaces or fomites, and people, including healthcare workers, infected or colonized with *C. auris* shedding the organism. This could be one of the reasons of the outbreaks' spread and the difficulty in controlling them. In the *C. auris* outbreak reported from the United Kingdom in a neuroscience intensive care unit, with a total of 70 infected or colonized patients, the transmission of *C. auris* was found to be linked to reusable axillary temperature probes (Eyre *et al.*, 2018), confirming that this emerging pathogen can persist in the environment and be transmitted in health care settings.

Resistance to Disinfectant and Antiseptic Compounds

As stated above, contaminated surfaces may be a source of transmission of *C. auris*. Unlike other *Candida* species, *C. auris* is resistant to some disinfectant compounds commonly used in hospitals and healthcare facilities around the world, and this could be another reason that has made it difficult to control the outbreaks effectively. In consequence, the appropriate use of disinfectant compounds plays a major role in controlling the management and spread of this pathogen.

Although there are no established guidelines for decontaminating surfaces contaminated by *C. auris*, healthcare organizations have issued different recommendations. The CDC suggests the use of disinfectants effective against *Clostridium difficile* spores, while Public Health England suggests the use of sodium hypochlorite, alone or in conjunction with other products (Ku *et al.*, 2018). These recommendations have been based on an increasing number of studies, which demonstrated that sodium hypochlorite, peracetic acid, hydrogen peroxide and vaporized hydrogen peroxide resulted in the greatest reduction in *C. auris* CFU (Biswal *et al.*, 2017; Abdolrasouli *et al.*, 2017; Moore *et al.*, 2017; Cadnum *et al.*, 2017). On the other hand, acetic acid, ethyl alcohol, and quaternary ammonium compounds showed less effectiveness (Cadnum *et al.*, 2017). In addition, the use of mobile ultraviolet-C light room decontamination devices has been shown to be useful for killing *C. auris* from surfaces when used with a longer cycle time (30 minutes) and at a proper distance (2 meters) after patient discharge (de Groot *et al.*, 2019). The effectiveness of different

Table 2 Effectiveness of surface disinfectants against *C. auris*

Agent	Concentration	Contact time	Efficacy	Reference
Sodium hypochlorite (Clorox, Chlor-clean, HazTab)	≥ 1000 ppm 0.39%–0.65%, 10%	1 min	+++	Cadnum <i>et al.</i> (2017), Abdolrasouli <i>et al.</i> (2017), Moore <i>et al.</i> (2017)
Quaternary ammonium	2%	10 min	–	Cadnum <i>et al.</i> (2017), Biswal <i>et al.</i> (2017)
Peracetic acid - hydrogen peroxide (OxyCide)	1200 ppm	3 min	+++	Cadnum <i>et al.</i> (2017)
Ethyl alcohol (Purell disinfectant)	29.4 %	30 sec	+	Cadnum <i>et al.</i> (2017)
Acetic Acid	> 5%	3 min	+	Cadnum <i>et al.</i> (2017)
Hydrogen Peroxide (Oxivir Tb, Clorox)	0.5%, 1.4%	10 min, 1 min	+++	Cadnum <i>et al.</i> (2017)
Vaporized hydrogen peroxide (BioQuell)	8 g/m ³	60 min	+++	Abdolrasouli <i>et al.</i> (2017)
UV light (UV- 360 Room Sanitizer)	2 meters	30 min	+++	de Groot <i>et al.</i> (2019)

disinfectants against *C. auris* are summarized in **Table 2**. After contact with infected or colonized patients, hand hygiene using soap and water may require the subsequent use of alcohol-based hand sanitizer for maximal disinfection.

Epidemiology

C. auris was first reported in 2009 following isolation from the external ear canal of a 70-year-old woman in a Tokyo geriatric hospital. Molecular analyzes and chemotaxonomic studies indicated that this strain represented a new species (phylogenetically related to *C. haemulonii* in the Metschnikowiaceae clade), and the authors proposed *Candida auris* (Latin for “ear”) (Satoh *et al.*, 2009). Not long afterwards, the first three cases of bloodstream infection by *C. auris* were described in South Korea during a retrospective microbiology review (Lee *et al.*, 2011), including one case occurred in 1996 (the earliest known *C. auris* episode) and two cases in 2009. Isolates were initially misidentified as *C. haemulonii* and as *R. glutinis*, and were accurately identified as *C. auris* by molecular methods. Since then, candidemia episodes by *C. auris* have been reported from India (Chowdhary *et al.*, 2013), South Africa (Magobo *et al.*, 2014), Kuwait (Emara *et al.*, 2015), Venezuela (Calvo *et al.*, 2016), the United Kingdom (Schelenz *et al.*, 2016), the United States of America (Vallabhaneni *et al.*, 2016), Spain (Ruiz Gaitán *et al.*, 2017), Oman (Mohsin *et al.*, 2017), Pakistan (Lockhart *et al.*, 2017b), Israel (Ben-Ami *et al.*, 2017), Colombia (Parra-Giraldo *et al.*, 2018), Panama (Araúz *et al.*, 2018), United Arab Emirates (Alatoom *et al.*, 2018), Malaysia (Mohd Tap *et al.*, 2018), Germany (Kohlenberg *et al.*, 2018) and Greece (Stathi *et al.*, 2019). Infections by *C. auris* have also been described in Canada (Schwartz and Hammond, 2017), Japan (Iguchi *et al.*, 2018), Switzerland (Riat *et al.*, 2018), China (Wang *et al.*, 2018), Norway, Austria, Belgium and France (Kohlenberg *et al.*, 2018). Other countries such as Kenya, Thailand and the Netherlands have reported cases but detailed reports have not been published. Therefore, until August 31, 2019 *C. auris* has been reported from 35 countries in five continents; however, as this new species is misidentified by commonly available diagnostic methods, the burden of *C. auris* infection or colonization episodes is probably underestimated. **Fig. 1** shows the countries affected by *C. auris* infections since 1996, including published and unpublished single case reports. Since its first description, *C. auris* has become one of the most frequent causes of candidemia in some hospitals in India (Rudramurthy *et al.*, 2017), South Africa (Magobo *et al.*, 2014), Venezuela (Calvo *et al.*, 2016) and Spain (Ruiz-Gaitán *et al.*, 2018a). In South Africa it was the third most common cause of candidemia and was responsible for 14% of all cases during 2016–2017 (van Schalkwyk *et al.*, 2019). Outbreaks of *C. auris* infections have been reported in healthcare institutions in India (Anil Kumar *et al.*, 2014; Biswal *et al.*, 2017), the United Kingdom (Schelenz *et al.*, 2016), the United States (Vallabhaneni *et al.*, 2016), Venezuela (Calvo *et al.*, 2016), Pakistan (Lockhart *et al.*, 2017b), Colombia (Parra-Giraldo *et al.*, 2018; Morales-López *et al.*, 2017), Panama (Araúz *et al.*, 2018), Spain (Ruiz-Gaitán *et al.*, 2018a), and South Africa (Govender *et al.*, 2018) (**Fig. 2**). The largest outbreak reported in a single institution was observed in a Spanish hospital affecting more than 500 patients, including 90 episodes of candidemia and more than 400 colonized patients (Ruiz-Gaitán *et al.*, 2018a).

Phylogenetic analysis of isolates recognizes four distinct *C. auris* clades that cluster geographically and differ by tens of thousands of single-nucleotide polymorphisms (SNPs): The South Asian, South African, South American, and East Asian clades (Lockhart *et al.*, 2017b; Chatterjee *et al.*, 2015; Sarma and Upadhyay, 2017). Recently, an isolate representative of a potential fifth clade has been reported in a patient in Iran who had never traveled outside the country (Chow *et al.*, 2019). However, within the clades, high degree of relatedness was observed. With different clades from different geographical areas, it is suggested that the emergence of *C. auris* in each geographical region is independent and does not spread from a single source (Lockhart *et al.*, 2017b). The rise of *C. auris* as a human pathogen, however, is emerging simultaneously in five continents remains an enigma.

The ecological niche of *C. auris* is not known and although it has not been detected in the natural environment, related species have been detected in plants, insects, and sea/pool water (Jackson *et al.*, 2019). A recently published study suggests that the global transformation of *C. auris*, possibly a former plant saprophyte, into a deadly human pathogen may be due to global warming. This could have forced *C. auris* around the world to adapt to higher temperatures, making it easier to infect humans with the help of migratory birds acting as intermediary hosts and spreading agents (Casadevall *et al.*, 2019).

Fig. 1 Countries affected by *C. auris* infections since 1996–2019.

Fig. 2 Countries from which *C. auris* outbreaks have been reported as August of 2019.

Clinical Features

Colonization

C. auris has the ability to colonize multiple body sites including nose, mouth, ear canal, groin, axilla, rectum, urine, and wounds (**Fig. 3**). Persistent colonization is another characteristic of *C. auris* and has been isolated in patients for 3 months or more after initial detection despite the use of agents such as chlorhexidine, nystatin or echinocandins (Schelenz *et al.*, 2016; Vallabhaneni *et al.*, 2016).

Fig. 3 Anatomical sites and clinical samples in which *C. auris* has been isolated in different studies.

These facts suggest the need to isolate colonized patients and to carry out weekly surveillance cultures until discharge and upon readmission to health care facilities. Patient isolation may be discontinued after three weeks of negative surveillance cultures. In large hospital outbreaks, such as in the United Kingdom and New York City, the screening sites in patients with the highest diagnostic performance for *C. auris* were the axilla and groin. In contrast, in the Spanish outbreak, rectum and urine were the most frequently colonized sites by *C. auris* (see "Relevant Websites section"; Kenters *et al.*, 2019).

Risk factors for *C. auris* colonization including prolonged stay in intensive care units, mainly in endemic countries, and contact with previously colonized patients or environment. It has been reported that the contact time for the acquisition of *C. auris* can be as short as 4 hours, and invasive infections can be acquired within 48 hours after admission to the critical care unit (Sarma and Upadhyay, 2017; Schelenz *et al.*, 2016; Jeffery-Smith *et al.*, 2018; Kenters *et al.*, 2019). The use of empirical antifungal therapy in colonized patients is not indicated and should only be considered if the patient presents a rapid clinical worsening (Kenters *et al.*, 2019).

Clinical Presentation

The clinical presentation of invasive infections by *C. auris* is similar to that of other species of *Candida*, including a wide spectrum of manifestations: candidemia, meningitis, osteomyelitis, otomastoiditis, chronic otitis media, intra-abdominal infections, pericarditis, pleural effusion, vulvovaginitis and bone infection (Satoh *et al.*, 2009; Chowdhary *et al.*, 2017; Khan and Ahmad, 2017; Sears and Schwartz, 2017; Morales-López *et al.*, 2017; Jeffery-Smith *et al.*, 2018; Spivak and Hanson, 2018; Khatamzas *et al.*, 2019). However, candidemia is the most frequent clinical manifestation of *C. auris* infection, as reported in a meta-analysis which included 16 countries and 742 isolates (Sekyere, 2018).

In the majority of reported cases, invasive infection by *C. auris* occurs in patients with altered immunity (systemic lupus erythematosus, diabetes mellitus, psoriasis, ulcerative colitis, etc.) who are in critical condition or have undergone invasive procedures (central venous catheter, urethral catheter, venovenous extracorporeal membrane oxygenation or major surgery) (Lee *et al.*, 2011; Chakrabarti *et al.*, 2015; Calvo *et al.*, 2016; Vallabhaneni *et al.*, 2016; Abdalhamid *et al.*, 2018; Alatoom *et al.*, 2018; Das *et al.*, 2018). Likewise, in most cases there is a history of administration of broad-spectrum antimicrobial agents or antifungal agents prior to the invasive candidiasis onset (Lockhart *et al.*, 2017b; Rudramurthy *et al.*, 2017; Ruiz-Gaitán *et al.*, 2019b). Some candidemia episodes have been observed in patients with severe comorbidities, including hematologic malignancies and solid organ transplantation. Afterward, invasive infection should be suspected in septic transplant recipients previously colonized by *C. auris* or hospitalized in units with positive environmental cultures, all in order to establish an early and adequate antifungal treatment (Azar *et al.*, 2017; López-Vilella *et al.*, 2019).

Outcome

C. auris attributable mortality infection is arduous to establish as most patients have a wide variety of comorbidities and co-infections that make this estimate difficult (Sekyere, 2018). In *C. auris* candidemia episodes, the estimated overall mortality rates range from 28%

Table 3 Reported cases of infection by *C. auris*

Bone	6	Morales-López <i>et al.</i> (2017), Tsay <i>et al.</i> (2017), Ruiz-Gaitán <i>et al.</i> (2018a), Tan and Tan (2018), Heath <i>et al.</i> (2019)
Persistent candidemia and breakthrough fungemia	13	Ruiz-Gaitán <i>et al.</i> (2018a), Alatoom <i>et al.</i> (2018)

to 60% (Lee *et al.*, 2011; Chowdhary *et al.*, 2013; Calvo *et al.*, 2016; Lockhart *et al.*, 2017b; Ruiz-Gaitán *et al.*, 2019b; Barantsevich *et al.*, 2019). Likewise, it has been observed that independently of the type of infection or the host's immune status, delay in the starting of an adequate antifungal therapy, either by erroneous identification or late diagnosis, increase the mortality rate up to 35% (Morales-López *et al.*, 2017). In the limited number of candidemia episodes reported in pediatric patients, mostly preterm new-born from Asia and South America, the mortality rate raised 30% (Lee *et al.*, 2011; Chowdhary *et al.*, 2013; Calvo *et al.*, 2016; Warris, 2018).

Regarding complications related to candidemia, in the outbreak reported in Spain complications after or during candidemia were observed in up to 12% of the episodes including spondylodiscitis, ventriculitis and endocarditis. Interestingly, all cases appeared despite appropriate antifungal treatment (Ruiz-Gaitán *et al.*, 2018a).

Although the available data are scarce, in addition to candidemia, other deep-seated infections caused by *C. auris* have been reported: one episode of pericarditis, one case of *C. auris* infection from a donor after lung transplant, and four cases of peritoneal infection, meningitis or bone infection (Khillan *et al.*, 2014; Mohd Tap *et al.*, 2018; Heath *et al.*, 2019) (Table 3).

Treatment

C. auris poses a real treatment challenge due to its high antifungal resistance rates. However, antifungal treatment is not recommended for *C. auris* isolates when the evidence suggest colonization rather than infection. Unlike other *Candida* species, there are no therapeutic guidelines for *C. auris* infections and therefore therapeutic options should be considered on each patient individually. Furthermore, the CDC recommend consulting with an infectious disease specialist before treating a patient infected by this species. While *C. auris* exhibit multidrug resistance, most isolates respond to echinocandins. Therefore, *echinocandins*, at standard dosing, are recommended as first-line treatment of invasive *C. auris* infections in adult patients. Prior susceptibility testing, however, is always required (Chowdhary *et al.*, 2016). For neonates, CDC recommend 1 mg/kg/day of amphotericin B deoxycholate or 5 mg/kg/day of liposomal amphotericin B in unresponsive cases (Tsay *et al.*, 2017). If after 5 days of treatment, clinical or microbiological improvement is not achieved, switching to a liposomal amphotericin B (5 mg/kg daily) or a combination therapy (echinocandin plus liposomal amphotericin B) must be considered. In addition, azoles plus echinocandins *in vitro* combinations have also been effective against *C. auris* (Fakhim *et al.*, 2017).

To date the appropriate duration of antifungal treatment for invasive *C. auris* infection is not known. In patients with echinocandin therapy new metastatic septic foci (meningitis, endocarditis, arthritis) have been observed even weeks after blood cultures became negative (Ruiz-Gaitán *et al.*, 2018a). Therefore, close outcome monitoring of patients with *C. auris* candidemia and extension of treatment beyond that contemplated in the current clinical guidelines (Cornely *et al.*, 2012; Pappas *et al.*, 2016) are recommended.

Due to the common resistance to fluconazole and voriconazole, and the emerging resistance to amphotericin B and echinocandins in some countries, the need for *new antifungal drugs* with activity against *C. auris* is evident. Fortunately, a number of new antifungal agents that are undergoing phase 2 or 3 clinical trials that have also been shown to be effective against *C. auris*. Ibrexafungerp, formerly SCY-078, is the first orally bioavailable 1,3- β -D-glucan synthesis inhibitor with a potent antifungal and antibiofilm activity against *C. auris* isolates and *C. auris* biofilms (Larkin *et al.*, 2017; Berkow *et al.*, 2017). VT-1598, a tetrazole-based drug that inhibits the ergosterol biosynthetic pathway, has also demonstrated *in vitro* and *in vivo* activity against *C. auris* (Wiederhold *et al.*, 2019a). Manogepix (APX001) is novel antifungal agent that exhibits potent, *in vitro* and *in vivo*, antifungal activity against *C. auris* and other drug resistant fungal species by inhibiting the fungal wall protein Gwt1 (Zhao *et al.*, 2018; Hager *et al.*, 2018a; Berkow and Lockhart, 2018b; Arendrup *et al.*, 2018; Wiederhold *et al.*, 2019b). Finally, rezufungin (formerly CD101) is a new echinocandin with a long half-life allowing intravenous administration of once a week, furthermore CD101 possesses potent antifungal activity against *C. auris* (Berkow and Lockhart, 2018a; Hager *et al.*, 2018b; Lepak *et al.*, 2018).

Infection Prevention and Control

The rapid acquisition of *C. auris* in health-care facilities in association with its multi-drug resistance and the high mortality rates related to invasive infection by this emerging pathogen highlight the need of prompt implementation of *infection prevention and control* (IPC) measures. Recommendations for infection control are the same for a patient infected or colonized with *C. auris* since both pose a risk for transmission. Until now, these recommendations have been adapted from strategies implemented for other pathogens like *Clostridium difficile* and multi-resistant Gram-negative bacilli. Recently, two European groups have just published recommendations specifically elaborated for *C. auris* in the light of experience acquired in recent years (Kenters *et al.*, 2019; Alastruey-Izquierdo *et al.*, 2019).

The implementation of early and strict IPC measures is essential to prevent the spread of *C. auris*. Furthermore, immediate notification of *C. auris* isolation to clinical and infection control teams, as well as to health authorities, is essential to implement IPC measures at all levels in a timely manner. The initial IPC measure is to isolate patients infected or colonized in single-patient rooms; if single rooms are not available, patients with *C. auris* must be cohorted in the same room, unit or box. Furthermore, healthcare personnel should strictly follow *contact precautions* when caring infected or colonized patients, including strict adherence to hand hygiene practices and proper use of personal protective equipment (disposable long-sleeved gown and gloves). Hand hygiene should be performed at the point of care using alcohol-based handrub conform EN 1500 (Ku *et al.*, 2018). Besides, the number of staff caring for these patients must be minimized and the allocation of dedicated staff should be considered wherever possible (Ong *et al.*, 2019).

After identification of a *C. auris* case, all patients sharing the same room, unit or box must be screened for *asymptomatic colonization* in the axilla and groin, including any other relevant sites (e.g., nose, urine, rectum, throat, wounds and catheter exit sites). In colonized patients, at least two negative assessments should be performed one week apart to discontinue IPC measures (Kenters *et al.*, 2019; Alastruey-Izquierdo *et al.*, 2019). When transferring patients colonized or infected by *C. auris* to other healthcare facilities, the staff at the receiving facility should be notified to implement the appropriate IPC and screening measures.

Although there are fewer data on the effectiveness of antiseptics against *C. auris* for skin *decolonization*, in high-risk patients and/or before mayor surgery procedures, selective oropharyngeal and/or digestive decontamination may be considered with chlorhexidine, oral nystatin or other antifungal drugs, taking into account the susceptibility profile of each isolate (López-Vilella *et al.*, 2019).

Any reusable *medical equipment* used in patients infected or colonized by *C. auris* should be cleaned and disinfected after every single use and, where possible, dedicated equipment should be used. The cleaning and disinfection of affected *patient rooms* should be implemented trice a day with a product effective against *C. auris* (as mentioned above). Additionally, after the patient's discharge the terminal cleaning and disinfection effectiveness should be monitored by culturing the surfaces around the patient (Kenters *et al.*, 2019; Alastruey-Izquierdo *et al.*, 2019).

Conclusion

Since its first description in 2009, *C. auris* has emerged as a serious nosocomial health risk, with widespread outbreaks in numerous hospitals worldwide. *C. auris* has subsequently been reported from a multitude of clinical manifestations, including colonization, mucosal infections, deep-seated infections, candidemia and even death. Infections caused by *C. auris* have been documented in healthcare institutions in 35 countries and is listed as the second leading cause of blood infection outbreaks in some affected institutions. The lack of appropriate identification, protection and containment procedures at some institutions has allowed *C. auris* to spread across the globe. This emerging pathogen can survive for months on exposed surfaces and medical equipment and is able to develop resistance to different disinfectant compounds. Furthermore, *C. auris* is very resistant to antifungals and some strains have demonstrated high MICs to the three major classes of antifungal agents, a feature not seen before in other *Candida* species.

Immune Response to *Candida albicans* Infection

Alberto Yáñez, Celia Murciano, M Luisa Gil, and Daniel Gozalbo, University of Valencia, València, Spain

© 2021 Elsevier Inc. All rights reserved.

Glossary

Antimicrobial peptides Small soluble defense molecules, which constitute key elements of the innate immunity as they can directly kill bacterial, viral and fungal pathogens.

DAMPs (damage-associated molecular patterns) Danger signals, usually host biomolecules, generated in injured tissues that can initiate and perpetuate a non-infectious inflammatory response; many DAMPs are nuclear or cytosolic proteins/DNA released outside the cell or exposed on the surface of the cell following tissue injury.

Emergency myelopoiesis Infection-activated proliferation and differentiation of bone marrow hematopoietic and progenitor stem cells toward the myeloid lineage, with the development of other lineages (lymphoid and erythroid) inhibited, in order to replenish mature myeloid cells consumed during infection.

Fungal colonization Growth of *C. albicans* on host tissues (gastrointestinal and urogenital tract) leading to a commensal relationship with the immunocompetent host; high level of colonization (due to antibacterial chemotherapy and/or immunosuppression) precedes de invasive infectious process, which often involves translocation of the pathogen across the gut mucosa to the bloodstream.

IFN-gamma (interferon- γ or type II interferon) Pleiotropic cytokine, predominantly secreted by activated T cells (CD4+ Th1 and CD8+ cells), as well by innate lymphoid cells (ILCs) and another immune cells ($\gamma\delta$ T), which plays an essential role in both innate and adaptive immune responses, by activating a number of phagocytic cell functions that favor pathogen clearance during infection.

ILCs (innate lymphoid cells) A family of developmentally related innate immune cells that belong to the lymphoid lineage, and are characterized by their lymphoid morphology, a lack of myeloid and dendritic cell phenotypic markers, and absence of antigen T- and B-cell receptors; although these cells do not respond in an antigen-specific manner, are involved in tissue development and remodeling, and are emerging as important effectors of innate immunity by secreting a variety of cytokines, including IFN- γ , which depends on particular ILC subsets.

Inflammasomes Cytosolic multiprotein complexes, formed by a PRR (e.g., NLR), an adapter protein (e.g., ASC), and caspase 1; their assembly and activation are triggered in response to microbial (PAMPs) and non-microbial danger (DAMPs) signals leading to caspase-mediated proteolytic activation of pro-IL-1 β and pro-IL-18 into fully mature inflammatory cytokines.

Innate immune tolerance Down regulation of innate immune responses, such as proinflammatory cytokine production, probably through epigenetic changes, upon exposure of innate immune cells to microbial ligands; the

most studied example is the endotoxin tolerance induced by successive injections of bacterial lipopolysaccharide (LPS).

Lectins A class of proteins that function as receptors with special carbohydrate-recognition domains, which are able to identify and bind to carbohydrates and their conjugates, forming aggregates; they are widely found in plants and animals, including mammals, and depending on their structure and function are classified into four types: C-, P-, I- and S-type lectins.

Morphogenetic transition (yeast-to-hypha transition) Process by which dimorphic fungal species, as *C. albicans*, switch between two growth patterns depending on environmental conditions. The transition from budding yeast to filamentous growth (hypha) initiates with the emission by the yeast of a germ-tube (nascent hypha), and it is associated with changes in cell wall structure and composition and in the expression of virulence factors.

Opsonins Molecules that enhance phagocytosis by binding to microbial cells during infection, and to dead/dying self-cells; major opsonins are the complement system, antibodies and other molecules (as the mannose binding lectin) which aid the immune system by a variety of mechanisms: favouring clearance of pathogens and dead self-cells by macrophages and neutrophils, activating the complement system, and targeting cells for destruction by natural killer cells.

Phagocytic synapse Massive reorganization of membrane proteins coordinated by the actin cytoskeleton of phagocytic cells that occurs upon recognition of β -glucan particles (zymosan or yeasts) by dectin-1, which clusters the receptor in a synapse-like structure, required for activation of dectin-1 signaling; this allows phagocytic cells to discriminate direct microbial contact from soluble ligands.

PAMPs/MAMPs (pathogen/microbial associated molecular patterns) Conserved molecules, broadly expressed in pathogen, as well as in non-pathogen microorganisms (bacteria, fungi, virus), and absent in mammals, that constitute molecular signatures that trigger immune responses upon recognition by innate immune cells through PRRs.

PRRs (pattern recognition receptors) Receptors that are predominantly expressed in innate immune cells that sense microbial presence through recognition of PAMPs/MAMPs, allowing discrimination between self and non-self by using a limited number of receptors, and initiating innate defense mechanisms.

Trained immunity Prolonged enhancement of function of the innate immunity after adequate priming (recognition of microbial ligands by host receptors) leading to a functional reprogramming associated to epigenetic changes. Macrophages and monocytes are among the main cells of the innate

immune system that can be trained, leading to phenotypes better equipped to deal with the pathogen.

Type I interferons (IFN- α , IFN- β) Pleiotropic cytokine family, expressed by immune cells, that have diverse effects on innate and adaptive responses during infection; type I

IFNs are essential for defense against viral infections, but may be detrimental to a diverse range of microbial infections by impairing host resistance; their role during candidiasis has not been unequivocally established yet.

Introduction: *Candida albicans*, an Opportunistic Fungal Pathogen

The genus *Candida* includes more than 300 disparately related species. *Candida* spp. are found in a diverse range of environmental niches, but only about twenty *Candida* species can cause human disease. Of these, more than 90% of invasive infections are caused by the five most common pathogens, *C. albicans*, *C. glabrata*, *C. tropicalis*, *C. parapsilosis*, and *C. krusei*, being *C. albicans* the most common fungal pathogen for the immunocompromised host. The incidence of other species, such as *C. glabrata*, *C. tropicalis* and *C. parapsilosis* has increased in the past few years, and also, other *Candida* species have been described as emerging pathogens able to cause disease in humans (i.e., *C. dubliniensis*, *C. guilliermondii*, *C. kefyr*, *C. famata*, *C. lusitanae*, *C. auris*, among others) (Pelroth *et al.*, 2007; Daniel, *et al.*, 2014; Guinea, 2014; McCarty and Pappas, 2016). This review is focused on *C. albicans*, as the most prominent species causing candidiasis, based on frequency and virulence.

As a commensal harmless organism, *C. albicans* colonizes the mucosal surfaces of the body of approximately 50% of healthy individuals at any given moment. When the host defenses are impaired, the balance between the host and this commensal fungus may turn into a parasitic relationship. The nature and extent of the impairment of host immune responses determine the manifestation and severity of candidiasis, a term which includes superficial mucocutaneous (skin, oral, vaginal and gastrointestinal) infections as well as serious disseminated or invasive infections (blood-stream infection or candidemia and deep-seated candidiasis) with mortality rates that can reach 40% (Pelroth *et al.*, 2007; Pfaller and Diekema, 2007; Yapar, 2014).

C. albicans does not act as a passive element during the infectious process but actively participates in the establishment and progress of the infection by expressing a set of putative virulence factors, whose expression varies among strains and is often environmentally regulated. These fungal attributes include the yeast-to-hypha transition (morphogenetic conversion from budding yeast to the filamentous growth form or hypha), the secretion of hydrolytic enzymes (aspartyl-proteases and phospholipases, among others) and the cytolytic peptide toxin candidalysin, phenotypic switching (ability to switch between different cell phenotypes), antigenic variability, adhesion to inert (plastic) materials and host tissues and ligands, ability to develop biofilms, and immunomodulation of host responses (Naglik *et al.*, 2004; Mayer *et al.*, 2013; Poulain, 2015; Höfs *et al.*, 2016; Moyes *et al.*, 2016).

The fungal cell wall, as the outermost cellular structure, plays a major role in the interactions between the microorganism and the environment, including the host, and therefore in the pathogenicity of the fungus. The *C. albicans* cell wall is a complex and dynamic structure composed by a network of β -1,3 and β -1,6 glucans, chitin, and mannoproteins. Microfibrillar polymers (chitin and glucans) form a skeleton that accounts for its rigidity and morphology. Cell wall mannoproteins are attached to microfibrillar polymers and play a major role in fungal physiology, including interactions with the host. Mannan, a complex structure composed by polymers of mannose, is found in covalent association through N- or O-linkages with these cell wall proteins (mannoproteins), that expand the entire cell wall structure, from the periplasm to the external surface where they are dominant. The cell wall mannan of *C. albicans* contains α -1,2-, α -1,3-, α -1,6-, and β -1,2-linked mannopyranose units with few phosphate groups. Lipids are also present in the phospholipomannan complex (PLM), a type of extensively glycosylated glycosphingolipid with hydrophilic properties that plays a relevant role in host interactions. Significant differences in cell wall organization and composition have been described between budding yeasts and hyphae, such as chitin and β -glucan content, structure and exposure to cell surface, and mannan structure and mannoprotein expression (Gozalbo *et al.*, 2004; Poulain and Jouault, 2004; Ruiz-Herrera *et al.*, 2006; Arana *et al.*, 2009; Höfs *et al.*, 2016).

Host resistance to candidiasis involves the coordinated action of both innate and adaptive host immune responses, which are triggered following fungal recognition by immune and non-immune cells. Defense mechanisms are initially triggered by an inflammatory response mediated by the innate immune system that also induces and modulates the adaptive immune responses, which in turn regulates signals from the innate system. The most relevant aspects of these defense responses to *C. albicans* are described next.

Initial Recognition of *C. albicans*, Innate Immune Responses

C. albicans first entrance in the body occurs at the mucosal and epithelium surfaces. When the pathogen overcome this first barrier, *C. albicans* is recognized by resident immune cells, which trigger antifungal responses to attract and activate other immune cells in order to clear the fungus from the tissues.

PRRs Involved in *C. albicans* Detection

Candida sensing is based on a complex set of interactions involving a variety of host receptors, mainly PRRs (pattern recognition receptors), and fungal ligands considered as PAMPs (pathogen-associated molecular patterns). Major *C. albicans* PAMPs are cell wall components, such as the skeletal polysaccharides chitin and glucan (β -1,3-glucan and β -1,6-glucan) and mannan (mannoproteins); also, intracellular fungal components, such as nucleic acids (DNA, RNA), that are released following phagocytosis and killing of fungal cells, are ligands for some intracellular PRRs. Expression and cell surface exposition of some fungal PAMPs may differ between the yeast and hyphal forms of *C. albicans*, a phenomenon that determines significant differences in the immune responses triggered by both fungal morphotypes. Besides, expression of some fungal virulence factors is also co-regulated with the yeast-to-hypha transition, enabling the hyphae to be better equipped to develop the infectious process and to overcome the host immune responses (Poulain and Jouault, 2004; Poulain, 2015; Arana *et al.*, 2009).

The most relevant families of PRRs involved in *C. albicans* sensing are Toll-like receptors (TLRs), C-type lectin receptors (CLRs), and nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) (Fig. 1).

TLRs constitute a family of PRRs expressed by most immune cell types (innate cells such as neutrophils, monocytes, macrophages, dendritic cells, as well as by B- and T-lymphocytes and natural killer cells), and non-immune cells, such as epithelial and endothelial

Fig. 1 *C. albicans* sensing by innate immune cells. *C. albicans* yeasts and/or hyphae are sensed by a variety of PRRs that recognize fungal ligands (PAMPs). Extracellular fungal ligands (basically cell wall components, such as glucans, N-linked and O-linked mannan moieties, chitin) are recognized by plasma membrane receptors, such as TLRs (mainly TLR2 and TLR4), CLRs (dectin-1, dectin-2 and dectin-3, MR and others: mincle, SIGNR1), galectin-3 (an S-type lectin), and the integrin CR3. Intracellular fungal ligands (DNA, RNA), released upon phagocytosis and killing, involves recognition by TLRs located at the endosomal membrane. Receptors for complement fragments and particularly Fc γ R also contribute to the recognition of *C. albicans* opsonized cells. Soluble (serum) MBL also contributes to *C. albicans* detection by binding mannan moieties and promoting opsonization. The simultaneous recognition of various PAMPs triggers complex signal transduction pathways (not shown in detail) leading to activation of immune responses. Signaling through TLR/MyD88 and Dectin-1/Syk/Card9 converge in the transcription factor NF- κ B that activates expression of proinflammatory cytokines, whereas signaling through dectins, CR3, MR and Fc γ R induces phagocytosis of fungal cells. Other receptors, such as galectin-3, SIGNR1, mincle, contribute to these responses. Collaboration among receptors in recognition of yeasts or hyphae and cross-talk among signal transduction pathways determines the tailored immune response to *C. albicans*. The inflammatory response is also generated by inflammasomes, that induce caspase-1-mediated activation of pro-IL-1 β , a key cytokine in immunity against *C. albicans*; inflammasome complexes can be generated and activated following fungal recognition by some PRRs (Dectin-1, CR3, TLRs), and by endogenous molecules released following phagocytosis and phagosomal disruption. Other cytosolic receptors (NOD2, MDA5) also contribute to detection of fungal-derived ligands. CARD9: caspase activation and recruitment domain-containing protein 9; MyD88: myeloid differentiation factor 88; NF- κ B: nuclear factor- κ B; Syk: spleen tyrosine kinase; TRIF: TIR-domain-containing adapter-inducing interferon- β .

cells. Among TLRs, the plasma membrane-bound TLR2 (which forms homodimers and heterodimers with TLR1 and TLR6) and TLR4 recognizes mannan moieties associated to the fungal cell wall; β -1,2 mannosides present in phospholipomannan and mannoproteins constitute the major ligand for TLR2, whereas O-linked mannosyl residues, which are accessible on the yeast surface, are the ligand for TLR4 (Fig. 1). Endosomal TLR9, TLR7 and TLR3 sense microbial nucleic acids following endocytosis and pathogen degradation that causes release of DNA and RNA (Fig. 1). TLR9 recognizes DNA containing unmethylated CpG motifs (the high rate of methylation and low frequency of CpG motifs in mammalian DNA avoids its recognition by TLR9). TLR7, and probably TLR3, recognizes fungal RNA. Restriction of some TLRs to endosomal membrane is also critical for discriminating between self and non-self nucleic acids (Sasai and Yamamoto, 2013; Kawasaki and Kawai, 2014; Fradin *et al.*, 2015; Gil *et al.*, 2016).

C-type lectin receptors (CLRs) play critical roles in *C. albicans* sensing by innate immune cells, as they recognize special carbohydrate domains of the fungal cell surface (Fig. 1). Major ligands for CLRs are β -glucans and mannans. Dectin-1 is the receptor for fungal β -glucans, which is expressed by myeloid phagocytes, as macrophages, monocytes, dendritic cells and neutrophils; differential surface exposure and structural differences of β -glucans between yeasts and hyphae (or even between fungal strains) modulate their immunological properties. β -glucans are also recognized by human neutrophils through the integrin complement receptor 3 (CR3). Dectin-2, mainly expressed by macrophages, neutrophils and dendritic cells, is the functional receptor for N-linked α -mannan residues on the yeast and hyphal cell walls, and forms heterodimers with dectin-3, a CLR that recognizes α -mannans on the surface of *C. albicans* hyphae. Consequently, the simultaneous and differential recognition of mannans from yeasts and hyphae by dectin-2 and dectin-3, and the different accessibility of glucan to dectin-1 may account for differences in the immune responses triggered by yeast and hyphal forms of *C. albicans*. Highly branched N-linked mannosyl chains are also recognized by the mannose receptor (MR) expressed on macrophages; MR also participates in recognition of fungal chitin. DC-SIGN (dendritic cell-specific-ICAM-grabbing non-integrin) is a CLR present on myeloid cells, including dendritic cells, that recognizes also N-linked mannan. Mincle (macrophage inducible Ca²⁺ – dependent lectin) is another member of the dectin-2 CLR family, expressed on monocytes/macrophages and neutrophils, which is involved in *C. albicans* recognition, although its ligand has been not well characterized yet. Galectin-3 is an S-type lectin receptor on the macrophages that recognizes β -mannan domains present both in phospholipomannan and mannoproteins. Mannan-binding lectin (MBL) is a soluble serum CLR that binds mannan-moieties on fungal surfaces (Brown and Gordon, 2001; Brown *et al.*, 2002; Poulain and Jouault, 2004; Taylor *et al.*, 2007; Hardison and Brown, 2012; Miramón *et al.*, 2013; Netea *et al.*, 2015; Richardson and Moyes, 2015).

In addition to detect PAMPs on the cell surface or in the lumen of endosomes or lysosomes, there is a cytosolic detection system to sense infection, which includes NOD-like receptors (NLRs) and retinoic acid-inducible gene-I (RIG-I)-like receptors (RLRs). NOD2 is involved in the immune responses to chitin-derived components, and NLRs function as components of the inflammasomes, cytosolic multi-protein complexes that play an important functional role in the innate immune response to candidiasis (Fig. 1), and also have an effect on adaptive immune responses (Joly and Sutterwala, 2010; Joly *et al.*, 2012; Tomalka *et al.*, 2011). Recently MDA5, a member of the RIG-I-like receptors (a family of PRRs that sense cytoplasmic nucleic acids important for viral recognition) has been also described to play a role in immune responses to *C. albicans*, although the fungal ligand responsible for MDA5 activation has been not yet characterized (Jaeger *et al.*, 2015).

C. albicans cells usually express various cell-surface PAMPs whose expression may change among strains and morphotypes. Therefore, recognition of *C. albicans* by immune cells is a complex process that may involve the simultaneous or sequential activation of different PRRs. Consequently, collaboration among receptors in fungal recognition and crosstalk between intracellular signaling pathways may lead to the final tailored immune responses generated. As an example, some lectin receptors such as dectin-1, galectin-3 and SIGNR1 (a murine C-type lectin homolog of the human DC-SIGN) have been identified as TLR2 co-receptors to design a collaborative recognition or to modulate ligand specificity; similarly, dectin-1 and SIGNR1 may also collaborate with TLR4 in fungal recognition, and dectin-1 synergizes with TLR2 and TLR4 for cytokine production in human macrophages. In some cases, a physical interaction between receptors has been demonstrated, such as galectin-3 and TLR2 or galectin-3 and dectin-1, suggesting that galectin-3 may mediate the cooperation between dectin-1 and TLR2 (Gantner *et al.*, 2003; Ferwerda *et al.*, 2008; Netea *et al.*, 2008; Romani, 2011; Lionakis, 2014; Gil *et al.*, 2016). In addition, this complex network of *C. albicans* sensing receptors allows immune cells to respond to (1) whole fungal cells through interaction between surface PAMPs and PRRs, (2) fungal ligands generated following phagocytosis and fungal destruction (such fungal DNA and RNA), through endosomal PRRs, and (3) cytosolic-located fungal ligands released from phagolysosomes or DAMPs (damage-associated molecular patterns) generated by cellular damage during infection, through NODs/NLRs.

Innate Immune Responses to *C. albicans*

Upon recognition of *C. albicans* PAMPs by PRRs, signaling pathways are triggered to generate effector and secretory antifungal responses by immune cells. Signaling pathways for PRRs are well known in some cases, such as for TLRs and C-type lectins, whereas are still poorly understood in others (Hardison and Brown, 2012; Kawai and Akira, 2009; Kawasaki and Kawai, 2014; Kumar *et al.*, 2011). Briefly, TLR-mediated signaling activates pathways leading to the induction of genes for inflammatory cytokines, as TNF- α , IL-1 β , IL-6 and IL-12. Signal transduction starts with the recruitment of a set of intracellular TIR-domain-containing adapters that interacts with the cytoplasmic TIR domain of the TLRs. MyD88 (myeloid differentiation factor 88) is the universal adapter molecule, shared by all TLRs, except TLR3, that triggers inflammatory pathways through activation of the transcription factors NF- κ B and AP-1 (JUN), which in

turn induce the expression of inflammatory cytokines. TRIF is critical in the induction of type I interferon genes and interferon inducible genes by TLR3 and TLR4 through the activation of the transcription factor IRF3, whereas the transcription factor IRF7 induces type I interferon genes and type I interferon-inducible genes through TLR7 and TLR9 signaling. TLR-mediated signaling is essential for host protection against candidiasis; MyD88 knockout mice are extremely susceptible to *C. albicans* infections; deficiencies in TLRs, mainly TLR2, and others in a minor extent (TLR4, TLR2 coreceptors, TLR3, TLR7 and TLR9) also cause impaired immune responses to *C. albicans* infection, both in mouse and/or human, although the role of some receptors (as TLR9) may be redundant. Recognition of fungal RNA by TLR7 has a non-redundant role in host defense against candidiasis, as it is partially required for IL-12 production by an IRF1-dependent pathway (Villamón *et al.*, 2004a,b; Biondo *et al.*, 2012; Netea *et al.*, 2008, 2015; Gil *et al.*, 2016).

Dectin-1 induces intracellular signals leading to (1) production of inflammatory cytokines through NF- κ B activation (through Syk1/CARD9- or Raf-1-mediated signaling pathways), (2) Syk1-mediated activation of NLRP3 inflammasome that generates bioactive IL-1 β and IL-18 following caspase activation, and (3) phagocytosis and production of ROS (reactive-oxygen species, see below). Dectin-1 signaling is only activated by particulate β -glucans that cluster the receptor in a synapse-like structure (phagocytic synapse), which represents a mechanism to distinguish direct microbial contact from detection of soluble ligands. Besides, hyphae induce a less proinflammatory response than yeasts, probably due to masking of glucan exposure by mannan/mannoproteins (Brown and Gordon, 2001; Gantner *et al.*, 2005; Goodridge *et al.*, 2011; Ifrim *et al.*, 2013; Netea *et al.*, 2015). *In vivo* studies with dectin-1 knockout mice showed contradictory results about their susceptibility to systemic candidiasis (probably due to strain-specific differences in glucan exposure), whereas human dectin-1 deficient patients showed clinically mucocutaneous infections but not invasive fungal infections. Interestingly, CARD9 deficiency is associated with susceptibility to invasive candidiasis, both in mouse and humans, probably because CARD9 mediates signal transduction pathways downstream of CLRs other than dectin-1. Dectin-2 deficient mice were more susceptible to systemic candidiasis, and phagocytosis of *Candida* cells by macrophages lacking dectin-2 was moderately decreased (Gross *et al.*, 2006, 2009; Ferwerda *et al.*, 2009; Drummond and Brown, 2011; Drewniak *et al.*, 2013; Ifrim *et al.*, 2016). Mincle, which associates with Fc receptors for IgGs (Fc γ R) and signals through Syk/CARD9, appears to have a protective role during candidiasis due to cytokine production, but is not involved in phagocytosis (Wells *et al.*, 2008). MR mediates several antifungal activities (such as phagocytosis of yeast by DCs, and IL-17 production by human peripheral blood mononucleated cells), although its role in protection against candidiasis appears to be redundant (Hardison and Brown, 2012). DC-SIGN recognition of *C. albicans* leads to *in vitro* production of cytokines and activation of the respiratory burst, probably in collaboration with dectin-1, although its role *in vivo* during infection has not been reported (Takahara *et al.*, 2011, 2012). Interestingly, chitin sensing by NOD2, TLR9 and MR dampens inflammatory responses through the induction of anti-inflammatory IL-10 production, thus indicating that chitin recognition plays a critical role for immune homeostasis (Wagener *et al.*, 2014).

MBL binding on fungal surface initiates the lectin pathway of complement activation, by cleaving the complement factor 3 (C3) and opsonisation of the microorganism: MBL-dependent deposition of C3b and iC3 fragments promotes phagocytosis of *C. albicans* by neutrophils. Furthermore, MBL may also act as an opsonin directly recognized by complement receptor 1 (CR1) on the surface of neutrophils (Brouwer *et al.*, 2008; Li *et al.*, 2012). In addition, MBL is able to modulate proinflammatory cytokine and chemokine production by modifying the *C. albicans*/TLR-mediated signaling pathways (Wang *et al.*, 2013). In this context, it should be noted that *C. albicans* can induce all three pathways of complement activation (classical, alternative and lectin pathways), that lead to the phagocytosis of the C3b-opsonized microorganism. While alternative and lectin (MBL) pathways are considered as non-specific immune responses, classical complement pathway requires antibodies for activation, and can be considered as a specific immune response. Activated complement is unable to kill *C. albicans* hyphae during infection, probably due to the thick fungal cell wall which may block the formation of the membrane attack complex (C5-C9) and the direct lysis of *C. albicans*. In addition, complement plays a central role in *C. albicans*-induced cytokine production by peripheral blood mononuclear cells. Accordingly, deficiency in complement factors (such as C3 and C5) causes increased susceptibility to disseminated infection in mouse models, since activation of complement by invading fungal cells contributes to opsonisation and a proper cytokine and chemokine production (Mullick *et al.*, 2004; Speth *et al.*, 2008; Tsoni *et al.*, 2009; Ricklin *et al.*, 2010; Cheng *et al.*, 2012).

Mouse models of infection have shown that fungal cells in the bloodstream bind and activate platelets, which in turn produce immune mediators, such as the platelet factor 4 (PF4 or CXCL4) and the CC-chemokine ligand 5 (CCL5 or RANTES), which have antifungal activity; also platelet-enriched plasma causes inhibition of *C. albicans* growth. However, the possible role of platelets in antifungal host defense is far to be deciphered (Robert *et al.*, 2000; Drago *et al.*, 2013).

Different inflammasomes are known to be involved in the response to *C. albicans* (NLRP3, NLRC4, NLRP10). Activation of inflammasomes in immune cells (macrophages, DCs, and others) leads to caspase-1 mediated production of fully mature IL-1 β and IL-18 inflammatory cytokines. This production of mature IL-18 and IL-1 β can be also produced by non-canonical (caspase-8 and caspase-11) inflammasomes (Gross *et al.*, 2009; Hise *et al.*, 2009; Kumar *et al.*, 2009; Joly and Sutterwala, 2010; Joly *et al.*, 2009, 2012; Tomalka *et al.*, 2011). The production of proinflammatory IL-1 β differs from other cytokines and involves two steps: (1) transcriptional upregulation of pro-IL-1 β , as an inactive precursor, downstream from PRRs (above cited), and (2) proteolytic cleavage by caspase-1 to release active IL-1 β . Activating stimuli induce conformational changes in NLRs leading to inflammasome assembly, caspase activation and IL-1 β cleavage. *C. albicans* transition from yeast to hyphae has been shown to be necessary for Nlrp3 inflammasome activation. Furthermore, only hyphae secrete the cytolytic peptide toxin candidalysin, responsible of causing epithelial damage (see below), which has been shown to provide the second signal to activate the NLRP3 inflammasome (Kumar *et al.*, 2009; Joly *et al.*, 2009; Martinon, 2010; Schroeder *et al.*, 2010; Joly and Sutterwala, 2010; Kasper *et al.*, 2018). Mature IL-1 β can be generated also in inflammasome-independent manner at the site of infection: (1) by caspase-1 constitutively expressed by monocytes; (2)

by proteinase 3, expressed by neutrophils, and (3) by fungal-derived proteases that can also generate host-derived active IL- 1β *in vitro*, and probably during infection, leading to activation of immune system (Beausejour *et al.*, 1998; van de Veerdonk *et al.*, 2009; Netea *et al.*, 2009, 2014; Gross *et al.*, 2012; Gabrielli *et al.*, 2015).

Following recognition of fungal PAMPs, immune cells trigger a variety of effector mechanisms of defense against *C. albicans* infection in order to clear the invading fungi. These mechanisms involve the simultaneous and/or coordinated (spatially and temporally) contribution of different immune and non-immune cell populations.

Epithelial Cells: The First Barrier Against *Candida* Invasion

The first line of defense against microbial infections in mucosal surfaces are epithelial cells (Ross and Herzberg, 2016). An intact epithelium constitutes an effective mechanical barrier against tissue invasion by *C. albicans*. Epithelial cells are able to restrict fungal invasion by a variety of defense mechanisms that appear to be activated depending on the degree of tissue damage and invasion by *C. albicans* (Fig. 2). Epithelial cells produce, in the presence of yeast cells, a variety of antimicrobial peptides with potent antifungal activity (β -defensins, cathelicidin, alarmins), suggesting that the uppermost epithelial layers are able to prevent fungal growth and hyphae formation, thus maintaining the commensal status of *C. albicans*, without further activation of immune responses (Lilly *et al.*, 2010; Yano *et al.*, 2012; Naglik *et al.*, 2014).

When *C. albicans* cells overcome this first antifungal barrier, fungal cells can proliferate and invade the epithelial tissues, either by endocytosis (yeast and hyphae) or actively penetrating the epithelial cells (hyphae). Recognition by epithelial receptors, such as the E-cadherin and Her2 (human epidermal growth factor receptor 2), induces endocytosis of fungal cells, promoting tissue invasion and pathogenicity. However, endocytosis does not necessarily contribute to immune activation in a direct manner (Zhu *et al.*, 2012; Villar *et al.*, 2005; Moyes *et al.*, 2010; Naglik *et al.*, 2014; Swidergall and Ernst, 2014). Fungal invasion and tissue damage trigger immune responses, and although PRRs (such as TLRs, C-type Lectins and NOD-like receptors) are expressed by epithelial cells, their role in *C. albicans* recognition and in the consequent activation of immune responses remain to be elucidated in most cases (Fig. 2).

Fig. 2 Innate defense mechanisms triggered by *C. albicans* in mucosal surfaces. The commensal status of *C. albicans* yeast cells can be maintained at the mucosal surface of healthy individuals due to the antimicrobial peptides produced by epithelial cells (β -defensins and others), as well as by interactions with commensal microbiota. Yeast endocytosis by epithelial cells or phagocytosis by resident macrophages induce a small NF- κ B-mediated proinflammatory response, enough to restrict fungal proliferation and invasion. Increased fungal proliferation and formation of hyphae results in tissue invasion and damage. Candidalysin produced by invading hyphae activates, via indirect mechanisms, the epidermal growth factor receptor (EGFR), which signaling activates a strong inflammatory response through MAPK/c-Fos mediated signaling. Proinflammatory cytokines and chemokines recruit neutrophils and monocytes to the site of infection (red arrows) to fight against the pathogen either by phagocytosis and intracellular killing or by extracellular mechanisms (NETs). Other innate immune cells, such as NK, ILC and $\gamma\delta$ T cells, can contribute to fungal clearance by producing cytokines such as IFN- γ , IL17 and IL22 that in turn activate effector cells, recruit neutrophils and induce secretion of β -defensins.

A mechanism to discriminate between the yeast (commensal) and hyphal (invasive) forms of *C. albicans* has been described in oral epithelial cells (Moyes *et al.*, 2010, 2015; Naglik *et al.*, 2014). These epithelial cells orchestrate an innate response to *C. albicans* via the transcription factor NF- κ B (through TLR-mediated signaling pathway) and a biphasic mitogen-activated protein kinase (MAPK) response. Activation of the first MAPK phase is independent of the hyphal formation, and is due to the recognition of fungal cell wall moieties by PRRs (probably TLR4 and others) (Weindl *et al.*, 2007; Netea *et al.*, 2015). Activation of these MAPK pathways, which involve a low level and transient activation of JNK and ERK1/2, leads to the activation of the c-Jun (AP-1) transcription factor (with as-yet-unknown transcriptional effects). This early and low level of NF- κ B- and MAPK-mediated proinflammatory responses (production of chemokines and cytokines), and the antifungal effect of resident macrophages (as well as the antimicrobial peptides produced by epithelial cells) may be sufficient to stop tissue invasion and damage, thus maintaining commensalism and low fungal burdens. If this early and transient response fails to avoid fungal proliferation, when a burden threshold of *C. albicans* hyphal cells is reached, a second phase is triggered. The second MAPK phase, which is dependent on fungal burdens and hypha formation, involves a strong activation of MAPK pathways (JNK, ERK1/2 and p38) and the c-Fos transcription factor, leading to immune activation; both NF- κ B and c-Fos then up-regulate the production of cytokines, chemokines and other inflammatory mediators. This immune activation and secretion of proinflammatory cytokines (G-CSF, GM-CSF, IL-1 α , IL-1 β and IL-6), and chemokines (RANTES, IL-8 and CCL20) in oral epithelium induces neutrophil and monocyte recruitment as well as the production of a variety of antimicrobial peptides (as β -defensins or cathelicidin) which favor fungal clearance or reduction of fungal burdens back down below the threshold level of activation, and thus a return to the commensal state (Naglik *et al.*, 2014; Moyes *et al.*, 2015). This biphasic response seems to be a common mechanism enabling different human mucosal tissues to recognize *C. albicans* hyphae and initiate innate immune responses, as a similar (not identical) MAPK-based response is found in vaginal mucosa. Such biphasic response will allow epithelial tissues to remain quiescent under low fungal burdens while responding specifically and strongly to damage-inducing hyphae when burdens increase (Fig. 2). Hyphae-secreted candidalysin not only causes epithelial damage during mucosal infection, but also the activation of immune responses by epithelial cells. Candidalysin induces the phosphorylation of the epidermal growth factor receptor (EGFR), not by direct recognition, but via indirect mechanisms. EGFR activation leads to induction of MAPK signaling (via p38, ERK1/2) and the activation of c-Fos (Moyes *et al.*, 2016; Wilson *et al.*, 2016; Ho *et al.*, 2019).

It has been also shown that production of inflammatory IL-1 β by mucosal tissues is also mediated by NLRP3 and NLRC4 inflammasomes. Induction of both inflammasomes occurs in mice following oral challenge with *C. albicans*, and deficiency in either NLRP3 or NLRC4 results in a strong reduction of proinflammatory and antimicrobial peptide secretion in the oral cavity. However, NLRP3 and NLRC4 differentially function in the innate response to *C. albicans* infection: NLRC4 plays a prominent role in host protection from mucosal infection, whereas NLRP3 inflammasome plays a predominant role in protection against disseminated infection (Tomalka *et al.*, 2011).

Once inside the tissue, fungal cells first encounter tissue-resident macrophages which phagocytose and kill them, and also secrete proinflammatory cytokines and chemokines that recruit neutrophils. Therefore, clearance of invading fungal cells from mucosal tissues involves various effector mechanisms (Fig. 2): phagocytosis and killing by resident macrophages and by recruited neutrophils (see below) and killing by β -defensins and other antimicrobial peptides produced by epithelial cells. Besides, cytokines released by monocyte/macrophages (TNF- α , IL-1 β , IL-6 and others), and by adaptive Th1/Th17 cells are also important for host defense against disseminated candidiasis (see below).

Killing of *C. albicans* Cells by Phagocytes: Macrophages and Neutrophils

Effector and secretory responses of phagocytes to *C. albicans* are critical for the development of a protective host response. Macrophages orchestrate innate immunity by phagocytosing fungal cells and coordinating inflammatory responses. Phagocytes use a variety of surface receptors recognizing PAMPs and opsonins on the fungal surface. Major receptors involved in phagocytosis of non-opsonized fungal cells are the glucan receptors CR3 and dectin-1 (phagocytic synapse, above mentioned) and in a minor extent dectin-2, MR and DC-SIGN, whereas opsonized *C. albicans* are recognized by Fc receptors for IgG (Fc γ R) and complement receptors (CRs). Also, a soluble mannose-binding lectin (MBL) participates in *C. albicans* phagocytosis, either by binding to fungal surface and initiating the pathway of complement activation or by acting as an opsonin recognized by CR1 on neutrophil surface (Brouwer *et al.*, 2008; Tsoni *et al.*, 2009; Li *et al.*, 2012; Miramón *et al.*, 2013) (Fig. 1).

Tissue-resident macrophages act as key effector cells for antifungal defense. These macrophages phagocytize *C. albicans* cells and produce inflammatory cytokines and chemokines that recruit and activate other immune cells (monocytes, neutrophils, NK cells) at the site of infection. Early *in vivo* studies showed that macrophage-depleted mice were more susceptible to infection, measured as mortality rate and fungal proliferation in tissues (Bistoni *et al.*, 1986, 1988). Blood monocytes are recruited to the infected tissue and differentiate into proinflammatory macrophages and contribute to clearance of the pathogen; deficiency in chemokine receptors (CX3CR1 and CCR2) leads to increased susceptibility to disseminated candidiasis, both in mouse and human, due to an impaired monocyte recruitment, and therefore an impaired accumulation of monocyte-derived macrophages in infected tissues. (Miramón *et al.*, 2013; Höfs *et al.*, 2016). Phagocytosis of yeast or germ-tubes has distinct effects on the differentiation pathway of human monocytes to dendritic cells, indicating that impairment of this differentiation may constitute a mechanism for hyphae to elude the immune surveillance (Chiani *et al.*, 2000; Torosantucci *et al.*, 2004).

Neutrophils have a crucial role in protection against invasive candidiasis. Release of chemokines by epithelial cells and tissue-resident macrophages upon interaction with *C. albicans* leads to the recruitment of neutrophils to the site of infection.

Neutrophils constitute the most potent immune population cell in killing *C. albicans* and the only immune cells able to inhibit hyphae development from yeast cells; in fact, neutropenia is a major risk factor for disseminated candidiasis in humans, and mouse models of neutropenia have demonstrated an increased susceptibility to disseminated candidiasis (Brown, 2011; Lionakis, 2014; Miramón *et al.*, 2013).

The killing of *C. albicans* by phagocytes involves intra- and extracellular, as well as oxidative and non-oxidative mechanisms. Intracellular mechanisms require internalization of fungal cells into the phagosome. In macrophages, phagosomes are transformed into phagolysosomes (after fusion with lysosomes) with the consequent exposure of fungal cells to acidic pH that favors the activity of hydrolytic enzymes (cathepsin among others) against the pathogen. In contrast, the nascent phagosomes in neutrophils fuse with preformed cytosolic granules without major pH changes. Neutrophil granules contain a variety of antimicrobial proteins (elastase, lysozyme, myeloperoxidase, lactoferrin, gelatinase and defensins, among others), which alternatively can also be released into the extracellular environment to deal with non-phagocytized fungal cells (Brown, 2011; Aratani *et al.*, 2002; Miramón *et al.*, 2013).

Upon phagocytosis, a characteristic production of copious amounts of oxidants does occur. This oxidative burst involves formation, via NADPH oxidase and myeloperoxidase, of ROS reactive oxygen species (ROS: superoxide radical, hydrogen peroxide, hypochlorous acid) with a strong oxidative and damaging properties. These oxidative mechanisms are critical for killing fungal cells after phagocytosis. Besides, phagocytes also express nitric oxide-generating enzymes, as inducible nitric oxide synthase (iNOS) involved in production of reactive nitrogen species (RNS: nitric oxide and peroxynitrite, which is decomposed in nitrogen dioxide and hydroxyl radical), which also contribute to killing of *C. albicans* phagocytized cells (Aratani *et al.*, 2002; Brown, 2011; Miramón *et al.*, 2013).

In addition, neutrophils also use an extracellular mechanism to deal with the pathogen: the release of chromatin containing antimicrobial proteins (such as calprotectin), known as NETs (neutrophil extracellular traps). This DNA-containing fibril structures bind to and neutralize hyphae, providing a mechanism to deal with this fungal morphotype that is too big to be efficiently phagocytosed. Elastase contributes to release of NETs, and NET formation induce the release of antimicrobial substances from the granules of neutrophils (myeloperoxidase, lactoferrin, cathelicidin, and others mentioned above) (Urban *et al.*, 2009; Brown, 2011; Duggan *et al.*, 2015). It has been also demonstrated that NETs cause unmasking of the *C. albicans* hyphal β -glucans and trigger changes in the fungal cell wall architecture that enhance immune recognition by dectin-1 and probably by other host receptors; this remodeling of cell wall architecture enhances host responses but also contributes probably to protect *C. albicans* cells by strengthening the cell wall, and point to the concept that pattern recognition during infection is a dynamic process that depends on the host-pathogen cross-talk (Hopke *et al.*, 2016).

Based on studies with neutrophils from patients with defined genetic defects, it has been shown that human neutrophils have two independent pathways for *C. albicans* killing: (1) a ROS-dependent mechanism, required for clearance of opsonized *C. albicans* cells that depends on the Fc γ R pathway, whereas (2) a ROS-independent pathway involved in killing of non-opsonized fungal cells involves CR3 engagement and CARD9 ligation. Dectin-1 is dispensable for both killing mechanisms, suggesting differences in the neutrophil cytotoxic response to *C. albicans* between human neutrophils, where glucan is mainly recognized by CR3, and murine neutrophils, where dectin-1 is required to activate CR3 for cytotoxic response to *C. albicans* (van Bruggen *et al.*, 2009; Li *et al.*, 2011; Gazendam *et al.*, 2014).

Innate Lymphoid and $\gamma\delta$ T Cells

Innate lymphoid cells (ILCs) are emerging as important effectors of innate immunity (Spits *et al.*, 2013). Natural killer (NK) cells, a prototypical ILC population that contribute to the rapid innate immune response to invading pathogens, are rapidly recruited at the site of infection. Proinflammatory cytokines and chemokines generated at the site of infection bind to their receptors on NK cells leading to their activation and to a rapid production and secretion of IFN- γ . NK cells also can directly recognize and respond to pathogen components through TLRs by secreting IFN- γ , although whether NK cells are stimulated directly by *C. albicans* cells remains unclear. Therefore, the antifungal immunity mediated by NK cells appears to occur by secretion of cytokines, such as IFN- γ , that activate phagocytic cells and also contribute to the induction of the appropriate adaptive immune response. Human NK cells are also activated following engulfment of fungal cells, leading to degranulation and release of GM-CSF, TNF- α and IFN- γ , and to fungal damage. However, activated NK cells are unable to inhibit filamentation or to kill the engulfed *C. albicans* cells, and direct antifungal activity of NK cells is mainly attributed to secreted perforin. GM-CSF production by activated NK cells in the spleen is also required to boost the *C. albicans* killing capacity of neutrophils in the kidneys and therefore to control the infection. Mechanistically, dectin-1 recognition of *C. albicans* by ccr2-dependent recruited inflammatory monocytes to the spleen, or by splenic dendritic cells, induces type-I IFN dependent-IL-15 production by monocytes, which places a pivotal role in the activation and GM-CSF release by splenic NK cells (Gozalbo *et al.*, 2014; Voigt *et al.*, 2014; Quintin *et al.*, 2014; Domínguez-Andrés *et al.*, 2017) (Fig. 3).

It has been also described that inactivated *C. albicans* cells *in vitro* inhibit activation of purified NK cells, and therefore this may be considered as a mechanism of fungal immune evasion or to avoid hyperinflammation in immunocompetent host (Murciano *et al.*, 2006).

Other ILCs are also relevant for controlling mucosal infection, such as IL-17-secreting ILCs (see below), that also secrete IL-22, as both cytokines enhance activation of mucosal antifungal immunity (Gladiator *et al.*, 2013; Netea *et al.*, 2015).

Fig. 3 Central role for IL-15 in protection against *C. albicans*. Systemic *C. albicans* infection in mice induces inflammatory Ly6C^{high} monocytes to leave the bone marrow, in a ccr2-dependent manner, to reach peripheral organs such as the spleen. In the spleen, *C. albicans* can be recognized by resident dendritic cells or by the attracted monocytes through dectin-1. Dectin-1 signaling induces the production of type I IFNs, whose signaling induces IL-15 production by the recruited Ly6C^{high} monocytes. IL-15 drives splenic NK cell activation and GM-CSF release through the circulation to the kidneys to stimulate iNOS production by neutrophils, which increases their candidacidal potential. This model reinforces the concept that type I IFN production is crucial for defense against systemic candidiasis and gives a critical role to IL-15 in the activation of the NK cell-neutrophil axis in the protection against *C. albicans*.

$\gamma\delta$ T cells, other innate-like lymphocyte subpopulation present in mucosal-associated lymphoid tissues, may contribute to immunosurveillance at the body surfaces. $\gamma\delta$ T cells can proliferate and produce IFN- γ and IL-17 in response to *C. albicans in vitro*, and therefore may play a role in defense of mucosal tissues against fungal infection. Mice deficient or depleted in these cells are highly susceptible to orogastric candidiasis. Also, natural Th17 (nTh17) cells (another subset of mature Th17 lymphocytes, which are distinguishable from inducible Th17 cells, and possess an intrinsic capacity for immediate activation in naïve host) play a role in immunity to oral candidiasis, probably by IFN- γ production and polarization towards a Th17 adaptive response (see below). Therefore, both $\gamma\delta$ T and nTh17 cells are mucosal sentinels that help in the control of mucosal pathogens, including *C. albicans* (Tanaka *et al.*, 2009; Conti *et al.*, 2014; Gozalbo *et al.*, 2014).

Microbiome and Anti-*C. albicans* Defense Mechanisms

The study *sensu stricto* of innate immune response to *C. albicans* in humans is somehow poorly understood, partly because humans are exposed to *C. albicans* early in life and develop adaptive responses. Skin and mucosal surfaces of healthy individuals are colonized by a variety of microorganisms (microbiota or microbiome), including fungal species (mycobiome), being *Candida* spp. (and *C. albicans*) highly prevalent in these surfaces (Cui *et al.*, 2013; Findley *et al.*, 2013; Underhill and Pearlman, 2015; Lagunes and Rello, 2016). This microbiota is part of the first line of antimicrobial defense of epithelial tissues, as members of this microbiota compete with pathogens for nutrients, surfaces and substrates. There is increasing evidence indicating that host microbiota also influences fungal colonization and antifungal immune responses (Oever and Netea, 2014; Romani *et al.*, 2015). As an example, some bacterial species (*Pseudomonas aeruginosa*, *Enterococcus faecalis*) are able to inhibit hypha development of *C. albicans*, and others (lactobacilli) inhibit fungal adhesion and growth, thus protecting gut mucosa from *C. albicans* proliferation. This complex relationship between microbiota and *C. albicans* is clearly deduced by the fact that treatment with antibacterial antibiotics with wide spectrum is a risk factor contributing to *C. albicans* colonization, and disturbances in normal microbiota can lead to mucosal infections in otherwise healthy hosts. Also, patients with chronic mucocutaneous candidiasis showed a decrease in bacterial species that normally colonize the skin (as *Corynebacterium* spp.) and increased presence of other bacteria (Kennedy and Volz, 1985; Oever and Netea, 2014; Smeekens *et al.*, 2014).

Conversely, changes or alterations in the immune system of the host are also associated with changes in microbiota composition, indicating the existence of a delicate balance between microbiota composition and host immune status. Truly life-threatening fungal infections are common only when this balance is disrupted, either by immunosuppression or genetic mutation (Iliev and Underhill, 2013; Oever and Netea, 2014; Romani *et al.*, 2015). Therefore, a three-way interaction between host, fungi and microbiota dictates the types of host-fungus relationship. In this context, it has been shown that members of normal microbiota can interact with epithelial cells inducing the production of cytokines (as IL-22) that favor resistance to *C. albicans* colonization (Zelante *et al.*, 2013); also mice lacking dectin-1 are more susceptible to chemically induced colitis, as a result of an altered response to endogenous fungi, and polymorphism in dectin-1 gene in humans is linked to severe ulcerative colitis (Iliev *et al.*, 2012); commensal *Saccharomyces cerevisiae* strains are able to induce trained immunity in monocytes, probably through

chitin-mediated signaling following phagocytosis of *S. cerevisiae* cells (Rizzetto *et al.*, 2016); TLR2 also modulates gut colonization and dissemination of *C. albicans* in murine models (Prieto *et al.*, 2016), and induces, upon recognition of commensal bacteria, antimicrobial peptides that are involved in murine gut resistance to *C. albicans* (Fan *et al.*, 2015).

In this context, it has been also demonstrated that the commensal microbiota impacts specific immune cell populations and their functions at peripheral sites, such as gut mucosal tissues. Germ-free mice displayed reduced proportions and differentiation potential of specific myeloid cell progenitors, leading to impaired early responses to pathogens. Therefore, gut bacteria direct innate immune cell development via promoting hematopoiesis, further linking microbiota, innate immune responses and hematopoiesis (Khosravi *et al.*, 2014).

Interestingly in an experimental model of evolutionary pressure, in which *C. albicans* was transferred through serial passages into the intestinal tract of antibiotic-treated mice, an accelerated fungal mutation was observed resulting in isolated variants of *C. albicans* with low-virulence phenotypes unable to form hyphae. Moreover, the obtained variants performed better as commensals and worse as blood-borne pathogens. Also, mice colonized with these variants were protected against virulent *C. albicans*, and different fungal and bacterial pathogens. Indicating that adaptive evolution of the fungus in the gut modifies host-pathogen interaction into a mutually advantageous relationship, in which both the microbe and the host gain some benefit from their interaction (Tso *et al.*, 2018).

As a conclusion, commensal microbiota plays an important role in promoting health by modulating host defense toward pathogens, including *C. albicans*, through host microbiota-immune system interactions.

Adaptive Immune Responses to *C. albicans*

In most cases, activation of innate responses by epithelial cells and phagocytes (macrophages and neutrophils) and NK cells is sufficient to restrict fungal tissue invasion from the colonized surface, therefore preventing disseminated infection. In other cases, innate immune mechanisms fail to control fungal infection and activation of adaptive immune responses are required to deal with the pathogen.

Dendritic Cells: Driving CD4⁺ T Helper Subset Differentiation

T lymphocytes (T cells) constitute an integral component of the host adaptive immunity in response to *C. albicans* infections that provide both direct and indirect means to control fungal proliferation. Activation of both CD8⁺ (CTL, cytotoxic T lymphocytes) and CD4⁺ T (T helper cells, Th) is controlled by dendritic cell (DC) populations. DCs patrol tissues where they can detect and phagocytose *C. albicans*. Following exposure to pathogens and/or inflammatory mediators, DCs are transformed into mature DCs which migrate efficiently from peripheral tissues into draining lymph nodes. At this location, DCs activate antigen-specific T lymphocytes, ultimately leading to both T cell expansion and differentiation of effector cells. Despite CTLs can inhibit *in vitro* proliferation of hyphal growth of *C. albicans* (see below), the major mechanism of adaptive immunity to *C. albicans* is the development of Th cell responses. The elevated prevalence of oropharyngeal candidiasis in AIDS/HIV⁺ patients where CD4⁺ T cells are depleted clearly shows the paramount importance of Th cell responses (Lee and Iwasaki, 2007; Fidel, 2011; Richardson and Moyes, 2015).

DCs are able to phagocytize and kill fungal cells (although less efficiently than macrophages), but their major role is the activation of Th cell responses through the processing and presentation of fungal antigens to naive CD4⁺ T cells, which can develop to four different subsets (Th1, Th2, Th17 and Treg) (Fig. 4). Development of each specific subset depends on the cytokines and the microenvironment present during CD4⁺ T cells priming by DCs at lymph nodes. Cytokine milieu drives differentiation to one specific Th subset while inhibits development of the others, and this Th polarization is critical for the outcome of the infection. Differential response to *C. albicans* yeasts and hyphae occurs following phagocytosis by murine DCs, as yeasts induce the production of proinflammatory IL-12 which drives polarization toward the Th1 subset, whereas ingestion of hyphae results in anti-inflammatory IL-4 production and drives Th2 development (d'Ostiani *et al.*, 2000; Montagnoli *et al.*, 2002). TLR/MyD88 mediated signaling (TLR2, TLR4, and endosomal TLR9) is involved in mounting a Th1 response. Despite DCs from MyD88 deficient mice are able to phagocytize fungal cells in a similar manner than wild type DCs, MyD88 is essential for IL-12 production, downregulation of IL-10, and antifungal Th1 priming, although individual TLRs may contribute differentially to these responses (Bellocchio *et al.*, 2004; Miyazato *et al.*, 2009; Gil *et al.*, 2016). Also, recognition of *C. albicans* by CLR, such as dectin-1, induce production of proinflammatory cytokines through SYK/CARD9-dependent and SYK-independent Raf-1 pathway that converge on NF- κ B to drive Th1 and, particularly, Th17 polarization (Gringhuis *et al.*, 2009; Robinson *et al.*, 2009; Richardson and Moyes, 2015). Initial differentiation toward Th17 phenotype is driven by IL-1 β , whereas IL-23 signaling is involved in maturation and terminal differentiation of Th17 cells (McGeachy *et al.*, 2009; Chung *et al.*, 2009). IL-23 and IL-6 are produced by DCs following recognition of *C. albicans* mannan, and favor Th17 differentiation (Smeekens *et al.*, 2010; Richardson and Moyes, 2015), and N-linked mannan has been found to be critically involved in DCs interaction with *C. albicans* (Cambi *et al.*, 2008). IL-1 β production involves the canonical NLRP3 inflammasome/caspase-1 and also caspase 8 which are activated upon recognition of fungal β -glucan by dectin-1 and CR3 on DCs, and drive protective Th1 and Th17 cellular responses to disseminated candidiasis (van de Veerdonk *et al.*, 2011; Ganesan *et al.*, 2014). Despite Nlrp10 is not involved in innate proinflammatory cytokine production, Nlrp10 deficient mice showed a profound defect in *Candida*-specific adaptive Th1 and Th17 responses, indicating a

Fig. 4 Adaptive T-cell responses to *C. albicans*. Recognition of fungal cells (yeasts or hyphae) by DCs through PRRs, such as TLRs (both plasma membrane and endosomal receptors, mainly TLR2, TLR4 and TLR9), and dectin-1 trigger MyD88- and Syk/Raf-1-mediated signaling pathways that activate transcription factors (NF- κ B, IRF5 and probably IRF1). NF- κ B induces expression of signal 1 (MHCII molecules), signal 2 (costimulatory molecules CD80/86) and signal 3 (cytokines) required for antigen presentation, as well as chemokines and inflammatory mediators, whereas IRF5 is involved in IFN β production, whose autocrine signaling through the IFNAR enhances signals 1, 2 and 3. In addition, these signaling pathways also lead to inflammasome assembly and activation, which causes caspase-1 mediated activation of IL-1 β . Simultaneously, DCs phagocytose and kill fungal cells, and processed fungal antigens are presented onto MHC II molecules to naive CD4 $^{+}$ cells. Recognition of the antigen by CD4 $^{+}$ cells through a T cell receptor (TCR) in the presence of costimulation from CD28 and CD80/86 is followed by cytokine polarization to specific Th subsets. This polarization strongly depends on the pool of cytokines secreted by DCs, which determines the fate of the Th subset polarization. Th1 and Th17 responses are associated to immune protection: Th1 is considered predominant in systemic/invasive infections, whereas Th17 is predominant in mucosal infections. Th1 and Th17 proinflammatory cytokines activate effector mechanisms to clear the pathogen by enhancing the fungicidal activity of phagocytes or recruiting and activating neutrophils respectively. Th2 is considered detrimental for protection, as Th2 cells secrete anti-inflammatory cytokines that favor fungal survival; however, Th2 cytokines are needed to avoid deleterious inflammatory responses and/or to diminish inflammation when infection is decreasing. Treg cells also participate in controlling adaptive responses, although their precise role is still not clearly determined. Production of IFN- β by DCs has been described also to participate in host protection (see text for further details).

role for this inflammasome in the generation of adaptive immune responses to fungal infections (Joly *et al.*, 2012; Eisenbarth *et al.*, 2012).

Therefore, signals triggered upon recognition of different PAMPs are integrated to define particular Th responses. The engagement of distinct receptors leads to disparate downstream signaling events that ultimately determines cytokine production, costimulation and Th responses. Consequently, selective challenge of receptors can be exploited for driving DCs toward a biased protective Th differentiation priming, with important implications in the design of DC vaccine-based strategies (Montagnoli *et al.*, 2002). DCs pulsed with fungal RNA induced protective immunity to *C. albicans* in assays performed to determine their potential role as anti-infective vaccine (Bacci *et al.*, 2002).

Th1 responses have been considered as protective against both mucosal and disseminated infection. Th1 cells secrete IFN- γ (and TNF- α , IL-2, among other proinflammatory cytokines) that has stimulatory effects on the phagocytosis and killing of *C. albicans* by neutrophils and macrophages, and also causes autocrine upregulation of IL-12 receptor, which in turn renders the Th cells more sensitive to IL-12, thus maintaining differentiation to Th1 phenotype (Smeltz *et al.*, 2002; Gozalbo *et al.*, 2014; Richardson and Moyes, 2015).

Th17 lymphocytes secrete numerous cytokines, including IL-17 and IL-22. IL-17 induces neutrophil recruitment and activation, and IL-22 enhances epithelial barrier function with release of β -defensins (Huang *et al.*, 2004; De Luca *et al.*, 2010). *C. albicans*-specific Th17 cells also produce IFN- γ , a cytokine that activates effector antifungal activities of phagocytes, as above mentioned

(Zielinski *et al.*, 2012). Th17 response is critical for protection against *C. albicans* infection at most mucosal surfaces, and chronic mucocutaneous candidiasis often develops in patients with disorders in Th17-mediated antifungal responses, whereas these patients do not show increased susceptibility to invasive candidiasis (Ferwerda *et al.*, 2009; Hernández-Santos and Gaffen, 2012; Hernández-Santos *et al.*, 2013; Smeekens *et al.*, 2013). Interestingly, Th17 responses are less relevant for protection against vaginal candidiasis in mice, as well as in humans, indicating the existence of differences in the anti-fungal responses among mucosal tissues (Yano *et al.*, 2012; Netea *et al.*, 2015). Overall, it is accepted that, while mucosal infections predominantly induce polarization of adaptive immunity to protective Th17 responses, systemic candidiasis is still considered to induce predominantly Th1 responses (Richardson and Moyes, 2015). Besides, another subset of Th cells (Th22) that secrete both IL-22 and TNF- α has been described to be important for cutaneous immunity to *C. albicans* (Eyerich *et al.*, 2011).

Th2 responses are generated in an anti-inflammatory environment (e.g., production of IL-4 by DCs in response to *C. albicans* hyphae). Anti-inflammatory cytokines produced by Th2 cells (IL-10, IL-4) inhibit Th1/Th17 development and deactivate phagocytic effector cells. Consequently, Th2 response has been considered as nonprotective against infections. However, Th2 cells are required for the maintenance of a balanced non-deleterious proinflammatory Th1/Th17 response, and to restore the non-inflammatory status following fungal clearance (Mencacci *et al.*, 2001; Netea *et al.*, 2015).

Treg cells maintain peripheral tolerance and limit the effector responses to control excessive proinflammatory responses leading to immune-mediated tissue damage. The role of Treg cells during candidiasis has been not unequivocally established. The immunosuppressive effects of Treg cells can be blocked by TLR-activated DCs leading to a Th1 response (Lee and Iwasaki, 2007). Besides, Treg cells also express TLRs, and the presence of TLR ligands (e.g., during a *C. albicans* infection) cause temporarily expansion and abrogation of the suppressive phenotype of Treg cells, enabling the enhancement of immune responses (proinflammatory Th1 response); upon pathogen clearance (decrease of fungal ligands), the expanded Treg cells regain their immunosuppressive activity to restore the immune balance (Sutmoller *et al.*, 2006a,b). Th17 and Treg cells are reciprocally regulated during T cell differentiation and can act cooperatively against *C. albicans*, although the final response appears to be dependent on the infection site: Treg cells enhances Th17 protective responses to oropharyngeal candidiasis, while reduces resistance in systemic infections (Whibley and Geffen, 2014a; Whibley *et al.*, 2014b), supporting that Th responses to invasive and mucosal infections are different, as above mentioned.

More recently it has been demonstrated that type I interferons (IFN- α and IFN- β), which are known to inhibit viral replication and mediate protection against viral infection, also play a role in anti-*Candida* host defense. Using mouse models, it has been shown that DCs are able to mount a type I IFN response against *Candida* spp. that requires phagosomal TLR7-mediated IFN- β signaling, and promotes persistence of *C. glabrata* in the host, and that IFN- β production inhibits fungal clearance in mice infected with *C. parapsilosis* (Burgeois *et al.*, 2011; Patin *et al.*, 2016). Similarly, mice lacking a functional IFN-I receptor showed a remarkable protection against invasive *C. albicans* infections and this detrimental role for type I IFN is associated with a reduced recruitment and activation of inflammatory monocytes and neutrophils (Majer *et al.*, 2012; Stifter and Feng, 2015). However, type I IFN has been described also to be beneficial for the immune responses to *C. albicans*; production of IFN- β by DCs, which is largely dependent on dectin-1 and dectin-2 signaling (via Syk and IRF5), is crucial for immunity to *C. albicans* by promoting the mobilization of neutrophils to the kidney (Biondo *et al.*, 2011; Del Fresno *et al.*, 2013).

Recently, it has been shown that type I IFNs, secreted by β -glucan-stimulated DCs via dectin-1, induce the proliferation and activation of CD8⁺ cells. The type I IFNs act in an autocrine manner via their receptor (IFNAR) to promote the presentation of exogenous antigen on MHC I molecules, surface expression of the co-stimulatory molecules CD40 and CD86, and the release of other cytokines, including IL-12 p70, IL-2, IL-6, and TNF- α (Hassanzadeh-Kiabi *et al.*, 2017). Consequently, these results support a protective role of type I IFNs during candidiasis. Therefore, the role of type I IFN in response to *Candida* infections might differ among fungal species, and the specific roles of type I IFNs in *C. albicans* infections requires further research. During bacterial infections, low level of type I IFNs may be required at an early stage to initiate cell-mediated immune responses, whereas high concentrations have immunosuppressive effects, such as the reduction of responsiveness of macrophages to activation by IFN- γ (Stifter and Feng, 2015). It should be noted that type I IFN genes are also induced through signal transduction pathways initiated by some TLRs (TLR4 and TLR2 via IRF3, and TLR7 and TLR8 via IRF5), although their involvement in development of adaptive responses to *C. albicans* infection remains to be determined. Moreover, findings obtained by integrating transcriptional analysis and functional genomics also indicate that type I IFN pathway is a main signature of *C. albicans*-induced inflammation and plays a crucial role in anti-*Candida* host defense in humans, probably by eliciting antifungal responses of macrophages and NK cells (Smeekens *et al.*, 2013).

CD8⁺ T Cells

Murine models of infection indicate that CD8⁺ cells also have a role in protection against candidiasis, both mucosal and disseminated infections. The main antimicrobial effector mechanisms of CD8⁺ T cells are cytotoxicity (by production and release of cytotoxic granules containing perforins and granzymes) and cytokine secretion (TNF- α and IFN- γ). The role of cytotoxicity in host defense against fungal infections is not well delineated, whereas the activity of cytokines is better understood. The protective effect is most probably due to the production of IFN- γ , whose production is induced by IL-12 (Benoit *et al.*, 1995; Ashman *et al.*, 1999; Gozalbo *et al.*, 2014). As above cited, activation of CD8⁺ cells can be promoted by DCs through autocrine type I IFN signaling upon recognition of fungal β -glucan by dectin-1 (Hassanzadeh-Kiabi *et al.*, 2017).

Humoral Responses: Antibodies

Soluble (humoral) proteins, mainly complement and antibodies, also contribute to defense against candidiasis, as components of the innate and adaptive immune responses, respectively. While cellular adaptive responses play a major role in host defense against *C. albicans* infection, the contribution of adaptive humoral immune mechanisms mediated by antibodies secreted by B cells (B lymphocytes) play relatively minor role in immune protection against the fungus (Netea *et al.*, 2015; Richardson and Moyes, 2015).

Although binding of antibodies to fungal surface antigens triggers activation of the classical complement pathway (above mentioned), the role of anti-*Candida* antibodies, as an important arm of the adaptive immunity, in host defense against candidiasis is paradoxical. Cell wall-associated components (glucans, mannans, mannoproteins) are major *Candida* antigens, as well as secreted enzymes (such as aspartyl proteases) or cytosolic fungal proteins (such as heat-shock proteins and glycolytic enzymes). Multiple antifungal activities are associated to anti-*Candida* antibodies, depending on the function of their antigens in fungal biology (adhesion to host tissues, germ-tube formation, acquisition of iron, proteolysis, etc.), as specific antibodies interfere with this function and therefore affect the host-pathogen interactions by inhibiting/neutralizing fungal virulence factors (Martínez *et al.*, 1998; Chaffin *et al.*, 1998; Gozalbo *et al.*, 2004). In fact, it has been shown that a variety of anti-*Candida* antibodies (anti-mannan, anti-Als3, anti-Hsp90, anti-SAP, anti- β -glucan), including both mouse and human antibodies, are able to confer some protection in animal models of mucosal and/or disseminated infection, and accordingly, some vaccination assays have shown a decreased susceptibility to infection in animal models (Paulovicová *et al.*, 2014; Moragues *et al.*, 2014; Wang *et al.*, 2015). Despite these observations, B-cell deficiency in mice does not confer increased susceptibility to *C. albicans* infection, and patients with agammaglobulinemia or hypogammaglobulinemia do not show increased susceptibility to fungal infection, indicating that humoral response during infection has a very modest role in host protection. However, the use of some purified antigens (Als3, Saps, glucan) in vaccination strategies imply presentation of antigens to the immune system in conjunction with suitable carrier proteins and adjuvants capable of eliciting the production of antigen-specific antibodies that, as above cited, may confer limited protection against infection (Moragues *et al.*, 2014; Wang *et al.*, 2015). Therefore, and due to the prevalence of fungal infections and their increase resistance to antifungal therapies, eliciting protective antibodies through vaccination remains as a viable strategy for improving resistance to *C. albicans* infections (Iannitty *et al.*, 2012).

Evasion of Host Defenses by *C. albicans*

In addition to induce the immune responses above described, *C. albicans*, as well as most pathogens, has developed strategies to try to avoid immune responses and to escape clearance from host defenses. These strategies include both (1) evasion of fungal recognition by shielding PAMPs that elicit immune responses, and (2) subversion of the normal immune responses. The main fungal mechanisms for immune evasion are outlined below.

C. albicans can enhance survival to killing by inhibiting phagolysosome maturation and oxide nitric production by macrophages (Collette *et al.*, 2014). In response to *C. albicans*, macrophages switch from an inflammatory phenotype (M1) to less inflammatory macrophages (M2), a change that might contribute to pathogenicity by decreasing immune responses (Reales-Calderon *et al.*, 2014).

The yeast-to-hypha transition is associated with changes both in cell wall composition and PAMPs exposure, as well as with changes in expression of virulence factors (adhesins, proteolytic enzymes, and others), making the hyphal morphology better equipped to resist immune responses. Hyphae induce a less proinflammatory response than yeasts, probably due to masking of glucan exposure by mannan/mannoproteins (Gantner *et al.*, 2005; van der Graaf *et al.*, 2005). In addition, the increased chitin content in hyphae may downregulate protective proinflammatory responses, thus favouring the infectious process (Wagener *et al.*, 2014).

C. albicans yeast and hyphae (germ-tube cells) interfere differentially with human monocyte differentiation into dendritic cells: while phagocytosis of yeasts inhibits their differentiation to DCs, phagocytosis of germ tubes give rise to monocyte-derived DCs which are unable to induce functional polarization of naïve T cells to effector cells. Therefore, phagocytosis of yeast and germ tube forms has profound and distinct effects on the differentiation pathway of human monocytes, indicating that their differentiation into DCs appears to be tuneable and exploitable by *C. albicans* hyphae to elude immune surveillance (Torosantucci *et al.*, 2004). Similarly, *C. albicans* β -glucans also causes the subversion of human monocyte differentiation into dendritic cells (Nisini *et al.*, 2007). As above mentioned, yeasts and hyphae have opposite effects on DCs, as phagocytosis of hyphae by DCs polarizes activation toward a Th2 cell response, subverting the protective Th1/Th17 response, thus enabling fungal persistence within the host (d'Ostiani *et al.*, 2000; Montagnoli *et al.*, 2002).

Induction of IL-10 and an enhanced Treg response (which has immunosuppressive effects), upon PRR (TLR2)-mediated *C. albicans* recognition has also been described to favor the infectious process (Netea *et al.*, 2004; Dillon *et al.*, 2006), despite TLR2 is a key receptor essential for resistance to *C. albicans* infection (Villamón *et al.*, 2004b; Gil *et al.*, 2016). Another probable mechanism of immune evasion are: (1) the production of a fungal soluble factor that *in vitro* reduces production of IL-17 by peripheral blood mononuclear cells, that could lead to dampen Th17 responses (Cheng *et al.*, 2010), (2) the secretion of proteolytic enzymes able to degrade substrates relevant for host protection (as complement components and antibodies) (Naglik *et al.*, 2004), and (3) the inhibition of the activation of NK cells, above mentioned (Murciano *et al.*, 2006).

C. albicans cells are also able to bind to a number of human plasma proteins and complement regulators (Factor H, FHL-1, C4 binding protein and plasminogen) through expression of fungal binding proteins (Gmp1, Pra1, Hgt1p, GpD2, and several plasminogen binding proteins). Those human proteins bound to fungal surface maintain their regulatory activities, and block

Fig. 5 *Emergency myelopoiesis and trained immunity during candidiasis.* During a systemic candidiasis, hematopoietic stem and progenitor cells (HSPCs) can directly detect *C. albicans* cells. This interaction stimulates HSPCs, through TLR2- and dectin-1-mediated signaling, to proliferate and bias their differentiation towards the myeloid lineage. Dectin-1 signaling in monocytes and in HSPCs induces trained immunity. Macrophages produced by them possess an enhanced ability to produce proinflammatory cytokines. Recognition of fungal β -glucan by dectin-1 in monocytes, and probably by HSPCs, triggers the Akt (protein kinase B)–mTOR (mammalian target of rapamycin)–HIF-1 α (hypoxia-inducible factor-1 α) pathway, modifications in metabolic pathways, and epigenetic rewiring. Induction of glycolysis resulting in lactate production is one of the central hallmarks in trained immunity metabolism. The cholesterol synthesis pathway appears to be an essential metabolic pathway as well, but not the synthesis of cholesterol itself, rather the metabolite mevalonate mediates training via the activation of mTOR. All these changes result in epigenetic modifications of histone marks H3K4me1, H3K4me3 and H3K27Ac, leading to changes in the expression of proinflammatory cytokine genes. Trained immunity has been shown to be protective against fungal infection or against unrelated pathogens (cross-protection).

complement activation and effector functions, opsonisation and phagocytosis, thus representing immune evasion mechanisms for the fungus to overcome host defense against infection (Meri *et al.*, 2002, 2004; Crowe *et al.*, 2003; Zipfel *et al.*, 2007; Luo *et al.*, 2009; Lesiak-Markowicz *et al.*, 2011).

Emergency Myelopoiesis and Trained Immunity

Myelopoiesis, the production of myeloid cells by bone marrow hematopoietic stem and progenitor cells (HSPCs), is essential during homeostasis to maintain reservoirs of innate immune cells and to replenish short living circulating cells for immune surveillance. During infection HSPCs must be activated to produce large quantities of neutrophils and monocytes to combat the pathogen and to replace the immune cells killed by the invading pathogen. In this context, HSPCs produce myeloid cells at expenses of the lymphoid and erythroid lineages in a process named “emergency myelopoiesis” (Takizawa *et al.*, 2012). It is well known that cytokine production by mature immune cells coordinates enhanced myelopoiesis during infection, but also direct interaction of microorganisms or their ligands, with HSPCs has been reported. Murine and human HSPCs express functional PRRs and their signaling pathways provoke cell cycle entry and myeloid differentiation (Nagai *et al.*, 2006; Sioud *et al.*, 2006). *C. albicans* detection by HSPCs can happen at the infected tissues, by the migratory HSPCs, or at the bone marrow by the circulating microbial components or by invading fungal cells. Direct interaction of *C. albicans* yeasts with HSPCs induces the proliferation and differentiation of HSPCs toward the myeloid lineage *in vitro* and *in vivo* (Fig. 5). This response requires signaling through TLR2 and dectin-1 and gives rise to functional phagocytes capable of engulf yeast cells and secrete proinflammatory cytokines (Yáñez *et al.*, 2009, 2010, 2011, 2013; Megías *et al.*, 2012, 2013). Interestingly, the interaction of *C. albicans* with HSPCs not only boosts myelopoiesis, but also influences the functional phenotype of the produced macrophages, following recently described observations of trained immunity for mature monocytes/macrophages. Priming monocytes/macrophages with *C. albicans* or with β -glucans induces trained immunity *in vitro* and *in vivo*, which confers to these cells an enhanced ability to produce proinflammatory cytokines after a second challenge (Fig. 5). Trained immunity plays a protective role against a secondary infection, and this effect can last weeks, months and even years. Therefore, trained immunity must take place also in HSPCs, upstream in the hematopoietic system. In fact, HSPCs-interaction with *C. albicans* gives rise to macrophages that are better prepared to deal with the infection, as they produce higher amounts of inflammatory cytokines and also have higher fungicidal capacity (Megías *et al.*, 2016; Martínez *et al.*, 2017, 2018).

Mechanistically, *C. albicans* β -glucan-recognition by dectin-1 induces trained immunity through the AKT, mechanistic target of rapamycin (mTOR) and hypoxia-inducible factor 1 α (HIF1 α) pathway. The activation of this pathway switches cellular metabolism from oxidative phosphorylation towards aerobic glycolysis, which is associated with a reduced basal respiration rate, increased glucose consumption and higher lactate production. Furthermore, β -glucans activate the cholesterol pathway, which accumulates the intermediate metabolite mevalonate responsible for inducing training via the activation of mTOR. Changes in glucose or lipid metabolism lead to epigenetic modifications underlying the enhanced secretion of pro-inflammatory cytokines (Fig. 5). Targeting innate immune

cells to regulate trained immunity could have therapeutic benefits in a range of immune-related diseases, including infectious and inflammatory processes and cancer (Netea *et al.*, 2011; Quintin *et al.*, 2012; van der Meer *et al.*, 2015).

Final Comments

During the last years much progress has been achieved concerning both innate and adaptive responses to *C. albicans*, as well as on the fungal ligands and host receptors (and signaling pathways) involved in these responses. However, there are still some issues that require further research for a complete and detailed picture of the immune responses to *C. albicans* infections. For instance: (1) how multiple signals from PRRs and cytokine receptors are integrated by immune cells to induce efficient mechanisms for fungal clearance?, (2) how is trained immunity generated and sustained during infection?, (3) how HSPCs behave during infection?, (4) how does mucosal and skin surface discriminate between commensal microbiota and pathogens, and how microbiota influences the infectious process?, (5) is it possible to design protective vaccination strategies or to generate antibodies appropriate for immunotherapy?

The answers to these, and other issues, are probably difficult to be discerned, taken into account that: (1) probably some signaling pathways overlap or are redundant for triggering host immune responses, (2) expression of fungal PAMPs (as well as virulence factors) may depend on *C. albicans* strains, due to the high genetic/phenotypic versatility showed by this species, thus representing an additional source of variability, (3) interpretation of the results obtained in *in vitro* assays, which have been an extremely useful tool for studying immune response to *C. albicans*, cannot be easily evaluated concerning their *in vivo* significance during infection, and (4) PRRs involved in *C. albicans* recognition may have physiological roles other than pathogen recognition, therefore the use of animal models with defective PRRs to study immune responses to *C. albicans* may lead sometime to difficult interpretations.

It should be also stressed that in rodents *C. albicans* is not a commensal, therefore providing an appropriate model to perform studies distinguishing innate and adaptive responses, whereas the study of innate immune response to *C. albicans* in human is more difficult, partly because humans are exposed to *C. albicans* early in life and develop adaptive responses. Furthermore, animal (murine) models have been widely used to study *in vivo* and *in vitro* immune responses to *C. albicans* and have contributed considerably to the present knowledge, although extrapolation to human is also difficult taken into account that murine and human immune systems are similar but not identical. More recently functional genomics (transcriptional analysis and system biology) has emerged as powerful tool that represents an alternative, unbiased approach to study antifungal immunity in humans, allowing identifying host defense mechanism occurring *in vivo*, as well as to establish the relationship between genetic immunodeficiencies and host responses to fungal infection.

Therefore, the study of the immune responses to candidiasis remains still as an exciting challenge for immunologists and microbiologists from both the basic research (immune responses and host-pathogen relationship) as well as from an applied point of view, as patients suffering candidiasis and the immunocompromised expanding population at risk require alternative immunotherapeutic approaches to deal with and/or to prevent infections.

Nomenclature

AIDS Acquired immunodeficiency syndrome

CNS Central nervous system

CSF Cerebrospinal fluid

EIA Enzyme immunoassay

GalXM Galactoxylomannan

GXM Glucuronoxylomannan

GXMGal Glucuronoxylomannogalactan

HAART Highly active antiretroviral therapy

HIV Human immunodeficiency virus

IFD Invasive fungal disease

LAT Latex agglutination tests

LFA Lateral flow immunoassay

Glossary

Basidium Filament that is formed during sexual reproduction in basidiomycetes and where meiosis occurs.

Capsule Structure that surrounds the cell body.

Free radical Molecular species that contains an unpaired electron in an atomic orbital.

Infection Introduction of a microorganism into a host.

Macrophage Type of leukocyte of immune system that is specialized in phagocytosis. Its function is to recognize, engulf and destroy target cells and foreign particles.

Melanin Dark pigment insoluble in water and resistant to heat, free radicals and acid widely found in nature, from mammals from microorganisms.

Meningoencephalitis Inflammation of the membranes of the brain and the adjoining cerebral tissue.

Phagocytosis Endocytic process that results in the internalization of solid particles inside the cell.

Serotypes Division within the same species that depends on the reactivity of a microbe to specific antibodies.

Titan cell Morphological transition defined as a massive growth a blastoconidia.

Virulence factor Element produced by a pathogen that causes damage in a host.

Yeast Unicellular fungus that divides by budding or fission.

Several fungal species have become a threat for susceptible patients because they can cause serious invasive diseases. Their incidence has increased in the last decades due to the raise in the number of immunosuppressed patients. The main causative agents of invasive fungal diseases (IFD) are yeasts and filamentous fungi (such as *Aspergillus* spp).

The main two yeast genera that can cause invasive diseases in humans are *Candida* spp. and *Cryptococcus* spp. While most *Candida* spp. live with the host as part of its microbiota, *Cryptococcus* spp. are acquired from the environment and infections by these yeasts have particular features that make them unique among fungal pathogens. The present chapter will focus on the importance of *Cryptococcus* spp. as pathogens, epidemiology, and main characteristics of the diseases they cause.

Cryptococcus Neoformans and *Cryptococcus Gattii*: Main Features

Cryptococcosis is a systemic disease caused by yeasts from the genus *Cryptococcus*. This genus comprises many species, but disease in humans is strongly associated with two of them: *C. neoformans* and *C. gattii*. These yeasts are part of the Phylum basidiomycete and infection occurs through inhalation of infective forms of yeast, the basidiospores, which are found in the environment (Negroni, 2012). Both species are very similar from a genetic and phenotypic point of view, but they present important differences in their epidemiology and virulence. They are both respiratory yeasts, and present an important difference in their cell wall compared to other fungal pathogens, because they have a low content of β -1,3-glucan. However, the main characteristic of *Cryptococcus* spp. is a polysaccharide capsule that surrounds the cell wall, which confers special immunogenic features to these yeasts.

Classification of *Cryptococcus Neoformans/Gattii*

The *C. neoformans/gattii* complex comprises two species that are subdivided and classified in different genotypes. These species have been also divided in serotypes according to different immunological properties of the capsule. *C. neoformans* has been classically divided in two serotypes: A (also denominated variety *grubii*), and serotype D (*C. neoformans* variety *neoformans*). In *C. neoformans*, AD hybrids are also very prevalent (Franzot et al., 1999). *C. gattii* contains serotypes B and C (Boekhout et al., 2001, 1997; Kwon-Chung and Varma, 2006). However, in the last years, several studies using molecular techniques have questioned the use of only two species among *C. neoformans/gattii* complex. Recently, Hagen et al. (2015) through phylogenetic and genotyping analysis,

proposed to recognize the current *C. neoformans* var. *grubii* and *C. neoformans* var. *neoformans* as two different species and, *C. gattii* in five separated species (Table 1).

Life Cycle

C. neoformans and *C. gattii* exist in two mating types, MATa and MAT α . However, the MAT α are predominant in nature and is most frequently isolated from patients (Kwon-Chung et al., 2014; Kidd et al., 2004). Sexual reproduction of these yeast species occurs through the propagation of haploid cells until there is contact between the opposite mating types in response to the production pheromones, a or α (McClelland et al., 2004; Stanton et al., 2010; Shapiro et al., 2011). The fusion of a and α cells induces the production of dikaryotic filaments, which eventually leads to the formation of a basidium. Meiosis occurs in this last structure and produces four chains of basidiospores that are ready to be dispersed in the environment (Kwon-Chung, 1975).

C. neoformans can also undergo the transition to a filamentous form during reproduction through another process called monokaryotic fruiting (Lin and Heitman, 2006). In this case, mating occurs when cells from the same mating type cells, a or α , become diploid (α/α or a/a), either by endoduplication or by nuclear fusion following cell fusion between two cells of the same mating type. Similarly to sexual reproduction, blastospores and chlamydospores also are produced during monokaryotic fruiting and meiosis occurs in the basidium (Fig. 1; Lin and Heitman, 2006).

Table 1 Current and last names of the species in the *Cryptococcus neoformans* and *Cryptococcus gattii* complex

Past species name	Molecular types/genotypes ^a	Serotype ^b	Current species name ^c
<i>C. neoformans</i> var. <i>grubii</i>	AFLP1/VNI AFLP1A and AFLP1B/VNII	A	<i>C. neoformans</i>
<i>C. neoformans</i> var. <i>neoformans</i>	AFLP2/VNIV	D	<i>Cryptococcus deneoformans</i>
<i>C. neoformans</i> hybrid	AFLP3/VNIII	AD	<i>C. neoformans</i> x <i>C. deneoformans</i> hybrid
<i>C. gattii</i>	AFLP4/VGI AFLP5/VGIII AFLP6/VGII AFLP7 and AFLP10/VGIV	B C B B and C	<i>C. gattii</i> <i>Cryptococcus bacillisporus</i> <i>Cryptococcus deutorogattii</i> <i>Cryptococcus tetragattii</i> and <i>Cryptococcus decagattii</i>

Epidemiology of Cryptococcosis

C. neoformans and *C. gattii* differ mainly in their epidemiology where *C. neoformans* affects mainly immunocompromised individuals. The human immunodeficiency virus (HIV) infection is the main risk factor to develop infection by *C. neoformans*. At the end of the 20th century, it was estimated that *C. neoformans* caused disease in around 80% of HIV patients in high-income countries (Pyrgos *et al.*, 2013; Sloan and Parris, 2014). The introduction of the highly active antiretroviral therapy (HAART) reduced the incidence of cryptococcosis in developed areas. However, the incidence and mortality rates associated with cryptococcal meningoencephalitis remain unacceptably high, ranging from 10% to 50%, depending on the clinical situation (Perfect *et al.*, 2010). Nowadays, cryptococcosis continues to have a high prevalence in developing areas, such as countries from Subsaharian Africa and Eastern Asia. In 2009, it was estimated that the number of deaths attributed to cryptococcosis was around 600,000 deaths per year (Park *et al.*, 2009). The clinical management of this disease in these countries, including the use of diagnostic tools that provide an early diagnosis, has reduced the mortality, but the current estimations are that this disease still causes hundreds of thousands of deaths worldwide (Rajasingham *et al.*, 2017). Even in those regions of Africa where the HAART treatment is available, 20%–60% of patients die from the disease and many individuals develop recurrent disease (Jarvis *et al.*, 2010). In the last few years, other groups of immunocompromised patients have been also identified (Sabiiti and May, 2012), such as patients with hematologic malignancies, organ transplant recipients, and patients affected by autoimmune diseases (Bratton *et al.*, 2013; Henao-Martínez and Beckham, 2015). Infection is acquired by inhalation of spores or dehydrated blastoconidia, such that yeasts first colonize the lungs. In healthy people, the infection is controlled by the immune system. However, it is not known if the yeasts are eliminated from the organism, or if they can remain as latent forms and cause asymptomatic chronic infections. The main risk for disseminated disease occurs in HIV+ patients with low number of CD4 T cells. In these situations, the yeast can disseminate through the blood and invade the central nervous system (CNS), where the blastoconidia can affect the meninges and disseminate through the cerebrospinal fluid (CSF). *C. neoformans* can also cause lesions on the brain mass leading to encephalitis and meningoencephalitis with the development of abscesses (cryptococcomas). The main symptoms associated with these infections are characterized by high fever, photosensitivity, severe headaches and convulsions. Meningoencephalitis is the most typical presentation of this disease and is found in over 70% of cases of cryptococcosis in patients with AIDS.

In contrast to *C. neoformans*, *C. gattii* has been traditionally associated with infections in immunocompetent individuals, although immunosuppressed patients are also at risk of infection (Jobbins *et al.*, 2010). Infections by *C. gattii* have been mainly reported as endemic in regions with tropical and subtropical climates. The infection is acquired from the environment by inhalation, but dissemination to the CNS is not frequent, and approximately 70% of patients suffer from pulmonary disease (Ngamskulrungrong *et al.*, 2012; Chen *et al.*, 2000). *C. gattii* has caused important outbreaks in animals and humans, as happened in the Vancouver Island from the British Columbia in Canada at the beginning of the 20th century (Fraser *et al.*, 2003). This outbreak was had a great impact in the fungal scientific community because it expanded through the North West area of the United States (Byrnes *et al.*, 2010).

Cryptococcus in the Environment

Cryptococcus spp. are isolated from multiple niches in the environment. *C. neoformans* has been associated with pigeon droppings, chickens, turkeys, wood, and hollow tree trunks (Anzai *et al.*, 2014). *C. gattii* is frequently isolated from *Eucalyptus* (Ellis and Pfeiffer, 1990) and other trees, although it can also be recovered from soil, wood debris, and air (Galanis *et al.*, 2010; Springer and Chaturvedi, 2010; Kidd *et al.*, 2004).

In nature, *Cryptococcus* has the ability to infect a wide range of hosts. It has been reported that *C. neoformans* and *C. gattii* can infect unicellular predators, such as amoebas, paramecium, flies, Lepidoptera, and mammals (mice, rats, koalas, dogs, and goats among others). To illustrate the variety of animals susceptible to *Cryptococcus*, this yeast can also infect aquatic animals, such as dolphins (Miller *et al.*, 2002), and even plants as *Arabidopsis thaliana* (Warpeha *et al.*, 2013). Infections of these hosts are important to understand the virulence and disease caused in humans, because it is believed that during the interactions with these alternative hosts, *Cryptococcus* has selected virulence traits that are used to infect humans. In this sense, it has been shown that in vitro exposure of *C. neoformans* to amoebas increase the virulence of the yeast in mice (Steenbergen *et al.*, 2003).

Virulence Factors

C. neoformans/gattii have several characteristics that allow for adaptation to the host and the development of the disease. First, this fungus can grow at 37°C; that allows thermotolerance and ability to replicate and disseminate at body temperature. In addition, *Cryptococcus* can also produce virulence factors that cause damage in the host. Some of them are lytic enzymes, such as phospholipase B, which contributes to fungal invasion in the host. This fungus also expresses urease, which allows growth in urea, and contributes to invasion of the CNS (Casadevall and Pirofski, 1999, 2003; Kronstad *et al.*, 2011). However, *Cryptococcus* is unique among yeast pathogens because it has two phenotypic characteristics that are the main virulence factors of this yeast: the capsule and melanin accumulation.

Cryptococcal Capsule

The polysaccharide capsule is the most characteristic phenotypic feature of *Cryptococcus*. This structure is easily visualized by suspension of the yeast in India Ink (Fig. 2).

Fig. 2 *Cryptococcus* cells with different capsule sizes. (A) Cells with small capsule and (B) cells with large capsule. Scale bar, 5 μ m.

The capsule is composed by two polysaccharides: glucuronoxylomannan (GXM) and galactoxylomannan (GalXM) (Zaragoza *et al.*, 2009), although this component also contains traces of glucuronic acid, so it was renamed to glucuronoxylomannogalactan (GXMGal) (Heiss *et al.*, 2009). Furthermore, a small proportion of mannoproteins and chitin-like structures are also present in the capsule. The polysaccharide is organized in fibers that attach to the α -glucan of the cell wall (Reese and Doering, 2003), although new polysaccharide is bound to the old polysaccharide fibrils through non-covalent interactions (Mcfadden *et al.*, 2006).

The synthesis and attachment of the capsule is a process that includes several steps, as biosynthesis, transport, and maintenance of the polysaccharide on the cell surface (Alspaugh, 2014). The basic components of the capsular polysaccharide are UDP-xylose, UDP-glucuronic acid, GDP-mannose, and glucuronic acid. These components are linked by the action of several enzymes, such as transferases and glycosidases. Furthermore, the polysaccharide fibers undergo other modifications, such as acetylation, xylosilation, and mannosylation (O'Meara and Alspaugh, 2012). Different genes involved in capsule biosynthesis have been identified. The first one, *CAP59* was described by Chang and Kwon-Chung (1994). In the following years, *CAP60*, *CAP64*, and *CAP10* genes were also identified as participating in the synthesis of capsular polysaccharide of *C. neoformans*. Mutants that do not express any of these genes are avirulent which confirms that the capsule is fully required to cause disease (Chang and Kwon-Chung, 1994, 1998, 1999).

The secretion of the polysaccharide fibers is a process poorly characterized. However, there is increasing evidence that the polysaccharide is exported inside vesicles that cross the cell wall and release its content outside of the cell (Rodrigues *et al.*, 2008). These extracellular vesicles seem to be involved in multiple processes, since they contain virulence factors, such as capsular polysaccharide and melanin (Eisenman *et al.*, 2009).

The capsule is highly dynamic in that it can change its structure and density depending on the environmental conditions and on the age of the cells (Zaragoza, 2011). These changes are of great importance for its virulence because they contribute to immune evasion and inhibit the penetration of proteins from the host immune system. The size of the capsule is not constant, and during the first hours of infection, there is a significant increase in capsule size (Feldmesser *et al.*, 2001). This process can be easily reproduced in vitro, and factors, such as low iron concentration, CO₂, nutrient limitation, and mannitol induce capsule enlargement. This process is important for the virulence because capsule growth inhibits phagocytosis and protects against oxidative stress (Zaragoza *et al.*, 2009).

The capsule is required for the virulence of *C. neoformans* and there is extensive evidence that acapsular strains are not virulent (Bulmer *et al.*, 1967; Fromtling *et al.*, 1982). The capsule confers protection against dehydration and oxidative stress (Aksenov *et al.*, 1973; Zaragoza *et al.*, 2008). Furthermore, it inhibits the phagocytosis of the fungus. However, in addition to its protective role, capsular polysaccharides are secreted and they exert multiple deleterious effects on the host. Among others, the capsular polysaccharides interfere with T-cell function (Feldmesser *et al.*, 2000; Rodrigues and Nimrichter, 2012), induce complement depletion and leukocyte apoptosis, and inhibit leukocyte migration and antibody production. Furthermore, both GXM and GXMGal induce immunomodulation and change the host immune response (Zaragoza *et al.*, 2009).

Melanin

Another important virulence factor described in *Cryptococcus* is melanin (Kwon-Chung *et al.*, 1982), which is a dark pigment widely found in nature, is acid-resistant and water insoluble. One of the main characteristics of this pigment is its role as antioxidant, so it confers protections against a large number of stresses.

In *Cryptococcus*, melanin is synthesized in the presence of diphenolic compounds (mainly L-DOPA) by the action of a diphenoloxidase encoded by two genes (*LAC1* and *LAC2*, being *LAC1* the most abundantly expressed). Melanin accumulates at the cell wall. In vitro, melanized cells are more protected against a large number of stresses compared to non-melanized cells, such as oxidants, uv light, ionizing radiation, antimicrobial peptides, heat, antifungal drugs, and phagocytosis (Nosanchuk and Casadevall, 2006). For this reason, melanin accumulation confers selective advantage during infection. Mutants unable to melanize have reduced virulence. Cryptococcal melanin contributes to the dissemination from the lungs to other organs (Salas *et al.*, 1996). Melanin precursors such as L-DOPA are abundant in the CNS, so it is believed that this could be one of the reasons for the neurotropism of these yeasts for this organ (Nosanchuk and Casadevall, 2003; van Duin *et al.*, 2004, 2002; Martinez and Casadevall, 2006; Zhu and Williamson, 2004;

Panepinto and Williamson, 2006). Recently, a new role has been attributed to melanin. Since this pigment can absorb energy, it has been shown that melanized cells can also absorb heat more efficiently than non-melanized cells, suggesting a mechanism by which melanized cells confers selective advantage at lower temperatures or in geographical regions far from the Tropics (Cordero *et al.*, 2018).

Cryptococcus as a Facultative Intracellular Pathogen

Although the capsule has antiphagocytic properties, the yeasts can be easily phagocytosed in the presence of opsonins that bind to the capsule, such as circulating antibodies and proteins from the complement system. Once phagocytosed, *Cryptococcus* can survive and replicate inside phagocytic cells (Diamond and Bennett, 1973), so it is considered a facultative intracellular pathogen. There are several mechanisms that allow intracellular survival. Initial studies suggested that *C. neoformans* does not inhibit phagolysosomal acidification, but rather resides and survives in the acidic phagolysosome (Levitz *et al.*, 1999). In agreement, when the pH of the phagolysosome is artificially increased, there is a reduction in the intracellular proliferation of the yeast, suggesting that *C. neoformans* has the ability to divide in acidic pH (Luberto *et al.*, 2001). However, recent studies using fluorescent probes sensitive to changes in pH have demonstrated that acidification of phagolysosomes containing cryptococcal cells is not full, which indicates that *C. neoformans* has the ability to interfere with the phagolysosome maturation. So far, two different mechanisms have been described for the cryptococcal-induced acidification inhibition. It has been shown that the capsule polysaccharide could “buffer” changes in phagolysosomal pH, inhibiting in this way its acidification (De Leon-Rodriguez *et al.*, 2018). Furthermore, *C. neoformans* can modulate phagolysosomal pH through urease and nitrogen metabolism (Fu *et al.*, 2018). Some other pathogen factors also contribute to intracellular survival. Capsule enlargement and melanin confer protection against free radicals and lytic peptides produced by the macrophages (Zaragoza *et al.*, 2008; Doering *et al.*, 1999). Melanin production also facilitates cryptococcal survival inside phagocytic cells because it can potentially neutralize cationic antimicrobial peptides and reactive oxygen species.

Cryptococcal survival inside macrophages results in multiple outcomes. Fungal cells can stay as latent forms within the phagolysosome, but they can also duplicate and proliferate. Exaggerate fungal replication can produce macrophage lysis, providing the microorganism an escape route from the intracellular environment (Johnston and May, 2013). However, fungal cells can also be expelled to the extracellular medium through a mechanism that does not involve macrophage death. This phenomenon is denominated non-lytic exocytosis or vomocytosis (Alvarez and Casadevall, 2006; Ma *et al.*, 2006). Non-lytic exocytosis occurs in both *C. neoformans* and *C. gattii* and shows great variation in incidence between strains (Alvarez and Casadevall, 2006; Johnston and May, 2013). Furthermore, this phenomenon also occurs in vivo (Nicola *et al.*, 2011). Finally, yeast cells can also be transferred between macrophages through a mechanism known as lateral transfer (Alvarez and Casadevall, 2006; Ma *et al.*, 2007), although this process remains to be fully characterized.

Formation of Titan Cells

Morphological changes in fungi, such as hypha development, play an important role during virulence because they contribute adhesion, dissemination and to immune evasion (Valero *et al.*, 2016; Coelho *et al.*, 2014; Trevijano-Contador *et al.*, 2016). In the case of *Cryptococcus*, filaments are only formed during sexual reproduction, but they are rarely present in tissues. During infection, most of the cells are found as rounded blastoconidia. However, there is large variation in the size of the fungal cells, that results in the appearance of cells of an abnormal large size denominated as titan cells (Fig. 3; Okagaki *et al.*, 2010; Zaragoza *et al.*, 2010; García-Rodas *et al.*, 2011).

Fig. 3 Image of *Cryptococcus neoformans* cells isolated from the lungs of an infected mouse. Scale bar, 10 μ m.

While the size of the cells in vitro is around 5–8 µm, they can reach up to 100 µm when residing in the lungs. These cells are polyploid and have an enlarged cell wall and capsule. Titan cells play a crucial role during cryptococcal infection for several reasons. Due to their size, they cannot be phagocytosed and are more resistant to stress factors, so these cells contribute to the long-term survival of the pathogen in the host. But it has been shown that these cells can also contribute to the disease because they polarize the host immunity to non-protective responses and inhibit the phagocytosis of fungal cells of regular size. Although there are few studies about the role of titan cells in patients with cryptococcosis, it has been shown that these cells were associated with higher CD4 T cell counts and reduced intracranial pressure, which led these authors to hypothesize that titan cells might be involved in the early stages of the infection (Fernandes *et al.*, 2018). This is in agreement with mouse experiments which demonstrated that during latent asymptomatic infection with *C. neoformans*, most of the fungal cells presented a “titan” phenotype in the lungs (Zaragoza *et al.*, 2010).

The characterization of titan cells has been limited to the fact that they needed to be isolated from animals and they were not efficiently induced in vitro. However, in 2018, three different groups described different laboratory conditions that stimulate cryptococcal growth, resulting in the appearance of cells that resemble titan cells from in vivo (Dambuza *et al.*, 2018; Hommel *et al.*, 2018; Trevijano-Contador *et al.*, 2018). These works highlighted new pathways and factors that regulate titan cell formation, such as mammalian serum, CO₂, iron and oxygen limitation and even the influence of bacterial commensal on this process.

Diagnosis and Treatment

Cryptococcal diagnosis is achieved through various methods. Proved infection is defined after direct examination of the fungus in India Ink suspensions in body fluids, mainly in CSF. However, this method normally provides the diagnosis at the late stage of the disease, so indirect tests that detect the capsular polysaccharides antigens are also available. Classically, two tests have been used: a latex agglutination tests (LAT) assay and enzyme immunoassay (EIA) test (Kambugu *et al.*, 2008; Boulware *et al.*, 2014). In 2009, a lateral flow immunoassay (LFA) was also developed. When compared to EIA and LAT, LFA provided a good reproducibility and prognosis, so it is now widely used nowadays in low-income countries (Hansen *et al.*, 2013; Perfect and Bicanic, 2015).

The treatment of cryptococcosis presents some limitations. There are three main antifungal families to treat invasive fungal infections: polyenes, azoles, and echinocandins, in addition to the nucleic acid inhibitor, 5-flucytosine (5-FC). However, not all antifungal agents available can be used in the treatment of cryptococcosis. *Cryptococcus* is intrinsically resistant to echinocandins and the therapy combined with AmB and 5-FC is not available in low-income countries. So treatment of cryptococcosis is based on an initial therapy with amphotericin B (AmB). However, AmB is toxic and can only be given to the patients for a limited time (around 2 weeks). There are lipid formulations that reduce its toxicity, but its high price limits its use in low-income countries, so treatment on these regions is mainly based on initial administration of conventional amphotericin followed by maintenance therapy with fluconazole, which could take several months to reduce the fungal burden of the patients (Perfect *et al.*, 2010).

Conclusions

C. neoformans/gattii are unique fungi due to their ability to infect a large number of hosts. These microorganisms still have a significant incidence in developing countries and mortality rates are high. The treatment is limited for several reasons, such as intrinsic resistance to echinocandins and price of antifungal drugs in developing areas. For these reasons, research on new therapeutic strategies to control cryptococcal infections is warranted.

Epidemiology of Infections Caused by Molds[☆]

Jennifer M Cuellar-Rodriguez, National Institute of Allergy and Infectious Diseases, Bethesda, MD, United States

Luis Ostrosky-Zeichner, Memorial Hermann Texas Medical Center, Houston, TX, United States

Awareness of significant life-threatening fungal infections has increased in recent years. However, given the global burden of these diseases (Bongomin *et al.*, 2017), and the morbidity and mortality associated to them, they are still heavily neglected in public health policy. We know that significant contributing factors to the epidemiology of mold infections, are host factors, geography, nosocomial reservoirs, and antifungal prophylactic strategies. (Dignani, 2014; Cornely, 2008).

There is a profound impact of these infections on population health and economics, and although true estimates of the economic burden of these diseases are lacking, estimates of invasive mold infections per se, has been attempted in a few, well designed studies, with the caveat that they have mostly been confined to restricted geographical areas or classically known at risk individuals (Azie *et al.*, 2012; Steinbach *et al.*, 2012). A recent study, trying to estimate the direct health care cost of fungal infections in the US (Benedict *et al.*, 2019), found that only in 2017, the cost for these infections where 7.2 billion, including hospitalizations and outpatient visits, where *Aspergillus* infections represented more than 25% of fungal related hospitalization costs, and the highest overall costs of any disease. These figures do not take in to account other costs, such as decreased productivity, disability and other indirect costs.

Given the difficulty in establishing invasive mold infections pre-mortem, current estimates are likely underestimating the magnitude of the impact of these diseases. No autopsies studies have established the burden of these diseases throughout different populations and different geographic regions; this is particularly relevant with the growing number of iatrogenic acquired risk factors and the potential of endemic regions as a result of climate change. In general, there are only few autopsies looking at invasive mold infections, thus true estimates are lacking. In a study looking at invasive fungal disease in published autopsies series from single center, multicenter or national studies, found a median prevalence of invasive fungal disease in 8.7 per 100 autopsies, where infections classified as *Aspergillus*-like infections, where the most common overall fungal diseases, followed by *Candida* spp. infections. These series included general population, hemato-oncologic patients, stem cell transplant recipients, and HIV/AIDS patients. In these series, the diagnosis of IFD, was established or suspected pre-mortem in only 30%–50% of cases. (Dignani, 2014).

We know that healthy individuals almost never develop significant mold infections, these are always considered opportunistic infections (Lionakis and Levitz, 2018). They occur either secondary to a disruption of the normal respiratory architecture and/or a decreased ability of the immune system of the host to contain these ubiquitous microorganisms. Invasive mold infections, of which the most prevalent are the ones caused by the *Aspergillus* genus, were traditionally thought to be confined to patients with severe immunosuppression, such as those with hematologic malignancies undergoing induction chemotherapy, hematopoietic stem cell transplant (HSCT) recipients, solid organ transplant (SOT) recipients, or patients with an inherited primary immune defect (PID). Other clinically significant mold infections are those caused by *Fusarium* spp, the agents of mucormycosis, *Lomentospora* spp., *Scedosporium* spp., and the dematiaceous molds. In the severely immunocompromised patient population, mortality for some of these infections often exceeds 50%, despite the availability of newer antifungals. (Seidel *et al.*, 2019; Roden *et al.*, 2005; Kontoyiannis *et al.*, 2010) Recently however, we have improved our recognition of other common risk factors for mold infections that were previously underestimated, and thus their true impact neglected. Some of these include, chronic pulmonary aspergillosis (Fig. 1) and invasive disease in prior or concomitant cavitory tuberculosis infections (Denning *et al.*, 2011; Hedayati *et al.*, 2015; Page *et al.*, 2019), in patients with chronic obstructive pulmonary disease (COPD) (Guinea *et al.*, 2010), as well as, undiagnosed invasive infections in non-hematologic critically ill patients.

On the other hand, not only our recognition of these diseases has improved, but there has been a true increase in the number of susceptible hosts. Classic at-risk individuals such as patients with hematologic malignancies live longer, and there is an expanding pool of individuals undergoing HSCT and SOT, worldwide (Gratwohl *et al.*, 2010; Rana and Godfrey, 2019). In addition, newer risk factors continue to be recognized (Table 1); precision medicine and the use of small molecules, targeted biologic therapies, and diverse cell therapies, including chimeric antigen receptor (CAR)-engineer T cells, have also expanded the pool of at-risk individuals (Ghez *et al.*, 2018; Varughese *et al.*, 2018; Zarakas *et al.*, 2019; Haidar *et al.*, 2019).

Aspergillosis

Invasive Aspergillosis

Estimates of invasive aspergillosis (IA) are complicated by the fact that most cases of IA in severely immunocompromised individuals are defined as “probable cases”, no microbiologic diagnosis exists, and estimates in different studies are not uniformly calculated (incidence, cumulative incidence, etc). Best estimates agree that invasive aspergillosis happens in ~ 2.6%–13% of patients with hematologic malignancies or marrow failure syndromes (Pagano *et al.*, 2010; Pagano and Caira, 2012; Pagano *et al.*,

Fig. 1 Chronic Pulmonary Aspergillosis (a) CT chest of a 52-year-old Mexican woman with rheumatoid arthritis, weight loss and chronic cough, with an apical cavitary lung lesion and weight loss. Initial diagnostic workup was negative, initially treated for pulmonary tuberculosis, without resolution. Surgical resection of the cavitary lesion showed tissue necrosis and hyphae surrounding the cavity. (b) GMS stain showed *Aspergillus*-like conidial heads. Culture grew *Aspergillus fumigatus*.

Table 1 Common and emerging risk factors for invasive mold infections

Mold	High risk	Intermediate risk
Aspergillosis	Chemotherapy Induced Neutropenia, Hematologic Malignancy (AML & MDS), SCT, GVHD, Corticosteroid, Lung Transplant, CGD, Btk-inhibitors	Aplastic Anemia, Liver Transplant, Severe Influenza Infection, Current or Prior Cavitary Tuberculosis, COPD,
Mucormycosis	Uncontrolled DM and Diabetic ketoacidosis, SCT, Lung Transplant.	Voriconazole prophylaxis, Other SOT, Penetrating Trauma, Cavitary Tuberculosis
Fusariosis	SCT, Hematologic Malignancy, Prolonged Neutropenia, GVHD, Treatment of underlying malignancy and/or SCT in Brazil.	Solid Organ Transplantation, Eye Trauma
Other hyaline molds	SCT, graft failure and retransplant. Lung Transplant, CF. Near drowning accidents	Azole prophylaxis

Source: AML, acute myelogenous leukemia; Btk, bruton tyrosine kinase; CGD, chronic Granulomatous Disease; COPD, chronic Obstructive Pulmonary Disease; CF, cystic Fibrosis; GVHD, graft-versus host disease; MDS, myelodysplastic syndrome; SCT, stem cell transplantation; SOT, solid organ transplant.

2006; Nucci *et al.*, 2018); in HSCT recipients in $\sim 1.3\%$ – 10% (Atalla *et al.*, 2015; Kontoyiannis *et al.*, 2010; Kojima *et al.*, 2004; Montoro *et al.*, 2019). Allogeneic HSCT recipients have a significant greater risk than autologous HSCT recipients; this increased risk results from the mean duration of neutropenia, and the immunosuppression used to prevent and treat graft versus host disease (GVHD). In addition to prolonged neutropenia, the intensity of the immunosuppression used to treat chronic GVHD is the single most important risk factor, for the development of invasive mold infections. Different surveillance studies have quantified the risk of invasive aspergillosis between $\sim 1\%$ and 9% in SOT recipients, however recent more accurate estimates, quantify the risk at about 1.6% (Kontoyiannis *et al.*, 2010; Pappas *et al.*, 2010). Given that most invasive aspergillosis is acquired through inhalation of fungal spores; in addition to decreased mucociliary clearance, and intensity of immunosuppression, lung transplant recipients on no anti-mold acting prophylaxis are particularly susceptible to this disease. About $\sim 9\%$ of lung transplant recipients develop an invasive fungal infection, and approximately 45% of these are due to *Aspergillus* spp. Mortality in this population remains unacceptably high (Seidel *et al.*, 2019; Pappas *et al.*, 2010; Aguilar *et al.*, 2018; Singh *et al.*, 2013).

In inherited immune deficiencies, chronic granulomatous disease represents the strongest risk factor for the development of invasive aspergillosis, and the risk correlates with the level of superoxide production. In large registries of primary immune deficiencies, IA remains a significant cause of mortality, despite best prophylactic strategies (Jones *et al.*, 2008), only in specialized centers has the mortality secondary to *Aspergillus* spp. infection truly decreased (Marciano *et al.*, 2015).

The development of cancer targeted therapies, such as small molecules, have improved the survival of diseases that previously had a dismal prognosis. However, for some of these therapies, there has been an unexpected rise in the number of aspergillus infections. In particular, patients treated with Bruton tyrosine kinase (Btk) inhibitors have been associated to an increased risk of IA. In a trial where ibrutinib was used for the treatment of primary central nervous system (CNS) lymphoma in conjunction to corticosteroids, 39% of patients developed invasive aspergillosis (Zarakas *et al.*, 2019; Ghez *et al.*, 2018). A significant number of other agents in this same pathway are currently under development, as such, the incidence of these infections will continue to rise.

Azole-Resistant *Aspergillus* Infections

Resistance to itraconazole was documented in the late 90's, possibly as a result of prolonged antifungal exposure (denning, d 1997 Antimicrobial agents and chemo). Slowly over the next 2 decades, resistance to azoles increased, including resistance to voriconazole, these in patients who had not necessarily been directly exposed to azoles. It was noted that this increase in resistance coincided with the widespread use of fungicides in agriculture, and although initial reports seemed to be confined to European countries, specifically the Netherlands (Trovato *et al.*, 2018; Buil *et al.*, 2019); azole-resistant *Aspergillus fumigatus* infections have now been described in all continents (Fig. 2; Resendiz Sharpe *et al.*, 2018; Friedman and Schwartz, 2019; Gonzalez-Lara *et al.*, 2019; Alastruay-Izquierdo *et al.*, 2018).

Chronic Pulmonary Aspergillosis (CPA)

Aspergillus fumigatus avidly colonizes structurally abnormal lung, in some patients, it may progress to cause tissue destruction, extensive fibrosis and loss of lung volume. Thus, chronic pulmonary aspergillosis represents a spectrum of infection and disease, that usually

Fig. 2 Countries where Azole-Resistant *Aspergillus fumigatus* has been Reported.

presents in non-immunocompromised individuals with a structural lung abnormality, either due to prior or current pulmonary disease, and present with pulmonary symptoms and elevated inflammatory markers over a prolonged period of time (Fig. 1). The most frequent underlying diseases are pulmonary tuberculosis, in which case patients can be misdiagnosed as having recurrent/refractory tuberculosis infection, chronic obstructive pulmonary disease (COPD), both common conditions worldwide, and sarcoidosis. It has been estimated that 10%–25% of patients with treated cavitary tuberculosis will go on to develop CPA, and about 1%–4% of patients without cavities after completion of anti-tuberculosis therapy (Denning *et al.*, 2011; Smith and Denning, 2011). Patients with COPD can develop CPA or invasive disease, invasive disease is more common on those on chronic systemic corticosteroids and broad-spectrum antibiotics (Guinea *et al.*, 2010), and about 20% of patients with COPD in whom aspergillus is isolated, go on to develop invasive disease. This may be an underestimate since there are no good biomarkers for IA in COPD patients, they rarely undergo biopsies and very few autopsies are performed. Recent estimates suggest the burden of CPA to be around 3,000,000 cases worldwide (Bongomin *et al.*, 2017).

Critical Care and Post-Influenza Aspergillosis

In addition to classic neutropenic patients, non-neutropenic patients, are being recognized as susceptible to *Aspergillus* infections, and a large proportion of these patients end up admitted to critical care units. Recent surveys suggest that clinically relevant aspergillus infections happen in 0.5% to 5.8% of all ICU admissions and it is associated to a very high mortality (~80%) (Bassetti and Bouza, 2017). It is hypothesized that the biphasic immune response to sepsis or multiorgan failure, includes a late state of immunosuppression, that can lead to invasive aspergillosis. In addition to classic at risk factors, other recently described risk factors are severe influenza infection, liver cirrhosis, and structurally abnormal lungs, such as COPD (Wauters *et al.*, 2012). In a large retrospective study of patients admitted to the ICU, influenza was an independent risk factor for invasive aspergillosis, and it was associated to a high mortality. In patients admitted to the ICU with influenza and immunocompromised, the incidence of IA, was up to 32%, and in those with influenza but without classically defined immunocompromise, the incidence was 14%, with an overall mortality of ~50% (Schauwvlieghe *et al.*, 2018). Awareness of these associations may lead to an earlier diagnosis, and potentially better outcome.

Mucormycosis

Mucormycosis is a disease caused by fungi in the order of the Mucorales; many species are known to be pathogenic in humans; *Rhizopus* spp is the most commonly globally isolated species. Other frequent pathogenic isolates include *Lichtheimia*, *Apophysomyces*, *Rhizomucor*, *Mucor* and *Cunninghamella* species (Prakash and Chakrabarti, 2019). Mucormycosis is still associated to an unacceptably high mortality rate. Overall all-cause mortality in patients with mucormycosis is around 50%, however this varies widely for different clinical presentation and hosts. Mortality is ~45% in sinus disease, ~75% in pulmonary disease, and >95% in disseminated (Roden *et al.*, 2005). Although recently there has been substantial development of newer antifungals targeting these infections, survival has not really improved (Webb *et al.*, 2018; Prakash and Chakrabarti, 2019). One of the main problems in the outcome of this disease is, early diagnosis, and although fungal biomarkers have been helpful in the earlier diagnosis of other more common fungal infections, this has not been the case for infections caused by the agents of mucormycosis. Reports of molecular diagnosis of invasive fungal infections may change this outcome, as well as the more widespread recognition of the need of a multidisciplinary approach to this disease (Cornely *et al.*, 2019). In terms of health care expenditure, average cost per hospitalization is generally higher for mucormycosis, than for any other mold infection (Benedict *et al.*, 2019). Mucormycosis largely predominates in patients with poorly controlled diabetes (mostly in the developing world) (Corzo-Leon *et al.*, 2018; Prakash *et al.*, 2019) and in transplant recipients (Prakash and Chakrabarti, 2019). However as with other mold infections, other risk factors are being recognized; post-pulmonary tuberculosis and alcoholism, were significant risk factors for mucormycosis in a large series from India. Although there is substantial geographic variation, HSCT recipients are at particular high risk, being the third or fourth most common invasive fungal infection in different series. In a North America multicenter cohort of transplant recipients, mucormycosis accounted for 8% of all invasive fungal infections in HSCT (Kontoyiannis *et al.*, 2010), and 2% in SOT (Pappas *et al.*, 2010). Gastrointestinal mucormycosis, is also associated to a very high mortality rate, although it has been described in all HSCT recipients and patients with diabetes, it is more common in pediatric patients with solid organ transplant (Dioverti *et al.*, 2015), very low birth weight and malnutrition (Prakash and Chakrabarti, 2019). Mucormycosis associated to penetrating trauma, carries the best prognosis, likely because it tends to occur in young healthy (non-immunocompromised) individuals (Roden *et al.*, 2005).

Health-care associated outbreaks of mucormycosis have occurred. These have been related to the use of contaminated hospital linens, gauzes, ostomy bags, contaminated steroid injections and construction. These outbreaks have been associated to high morbidity, in some cases mortality and high health care costs (Davoudi *et al.*, 2015). A recent multi-center study of pathogenic molds in freshly laundered hospital linens in 15 cancer and transplant centers in the US, found that linens were contaminated upon arrival in 47% of the centers; at individual centers, mucormycosis was isolated from 0% to 24% of health care linens cultured. Freshly laundered visibly soiled linens were associated to culture positivity (Sundermann *et al.*, 2019). How this translates clinically is difficult to assess, however at these institutions, where a large proportion of susceptible hosts are being hospitalized, more work is needed to secure patient safety.

Fusariosis

Fusarium is another highly pathogenic hyaline mold in immunocompromised individuals. It is found ubiquitously in nature and has a worldwide distribution, but there are areas of regional hyperendemicity. In immunocompetent individuals its responsible for a large number of the global burden of fungal keratitis and blindness, and some onychomycosis. In severe immunocompromise secondary to prolonged neutropenia, mostly patients with hematologic malignancies and HSCT recipients, it causes invasive disease (Nucci *et al.*, 2018; Atalla *et al.*, 2015; Nucci *et al.*, 2015). More recently it has also been recognized as a cause of allergic disease, similar to allergic bronchopulmonary aspergillosis (Chowdhary *et al.*, 2014; Deepak *et al.*, 2019), hypersensitivity pneumonitis and colonization of preexisting cavities, thus it behaves similarly to *Aspergillus* infections (Dickson and Tankersley, 2015; Lee *et al.*, 2000; Nucci *et al.*, 2015; Ramirez and Jacobs, 2014).

In prospective studies in the United States and Italy, the cumulative incidence of invasive fusariosis was around 0.1%–0.3%, in transplant recipients, and patients with hematologic malignancies, mostly acute myeloid leukemias and HSCT (Kontoyiannis *et al.*, 2010; Girmenia *et al.*, 2014a,b). In contrast, in studies conducted in Brazil, which is one of the regions with the highest reported prevalence of invasive fusariosis, the incidence in patients with hematologic malignancies and HSCT recipients was around 3.8%–5.2% (Atalla *et al.*, 2015; Nucci *et al.*, 2018, 2013). Skin dissemination is common among patients with invasive fusariosis, and fungemia can be documented in about 50% of patients with disseminated disease (Nucci *et al.*, 2003).

Fusarium keratitis is the leading cause of mold associated visual impairment and blindness, usually associated to occupational exposure (farmers), implantation injury (trauma) and contact lens wear (Bongomin *et al.*, 2017; Perez-Balbuena *et al.*, 2009; Hernandez-Camarena *et al.*, 2015; Gopinathan *et al.*, 2002; Das *et al.*, 2015). In underdeveloped countries, these infections can lead to high proportion of enucleation (11%) and visual loss (~50%) (Green *et al.*, 2007).

Other Hyaline Molds

Scedosporium and *Lomentospora* classically known to cause superficial soft tissue infections after trauma, and to be frequent respiratory colonizers in patients with underlying lung pathology (i.e., cystic fibrosis or cavitary lung disease), these molds can be highly pathogenic and cause invasive and disseminated disease in severely immunocompromised individuals, or cause CNS infections in patients with near drowning accidents (Seidel *et al.*, 2019, 2020; Ramirez-Garcia *et al.*, 2018). The majority of reports come from Australia, North America, Europe and Korea. Whether there is a true geographic distribution to these infections, similar to what happens with fusariosis, is possible, however there is probably significant underreporting in many areas of the world (Seidel *et al.*, 2019). Although significantly less common than other mold infections, they have emerged as a cause of severe invasive disease in the face of prophylactic antifungals, in particular, *Lomentospora prolificans*, which similarly to *Fusarium* spp can lead to fungemia. The intrinsic resistance to most currently used antifungals, pose a significant challenge in the treatment of this breakthrough fungal infections, which unless surgically treated are associated to a high mortality rate. As with other mold infections, these are more common in patients with hematologic malignancies, HSCT and lung transplant recipients. Cystic fibrosis patients can frequently be colonized with these molds, and to what extent this colonization contributes to the decline of the pulmonary function is unknown, however is it highly associated to the development of posttransplant invasive pulmonary disease. Lacerating eye lesions and penetrating trauma are significant risk factors in immunocompetent individuals (Seidel *et al.*, 2019, 2020; Ramirez-Garcia *et al.*, 2018).

Conclusions

Although significant advances have been made in understanding the epidemiology and global burden of mold infections (Bongomin *et al.*, 2017), accurate estimates based on surveillance data and not on population assumptions is still lacking for most of the developing world. In the last decade scientists driven efforts have contributed to decreasing the knowledge gap of the risk factors for these diseases, however, estimates of the true burden of these infections is still lacking, and the number of at-risk individuals will continue to change over-time. Prioritizing epidemiologic surveillance of these diseases around the globe, may have a significant public health impact, in the prevention and early treatment of these debilitating diseases.

Glossary

Aspergilloma A clump of fungus in a body cavity, such as the lungs.

Aspergillosis Set of diseases caused by *Aspergillus* spp. which comprises a variety of clinical manifestations.

Aspergillus fumigatus Fungus of the *Aspergillus* genus. One of the most common predominant human-pathogenic mold causing aspergillosis.

Biofilm Multicellular and multilayered hyphae which are embedded in an extracellular matrix.

Colonization Growth in the host without invasive infection. It is defined when there is a positive culture from bronchoalveolar lavage or two sputum cultures positive for the same *Aspergillus* species, in the absence of invasive pulmonary aspergillosis.

Conidia Asexual fungal spores of filamentous fungi.

Conidiophores Highly organized structures of fungi that successively produce conidia on characteristic conidial heads.

Host An animal or plant on or in which a microorganism or commensal organism lives.

Hydrophobins Hydrophobic proteins that are present on the surface of *Aspergillus fumigatus* conidia and are responsible for the typical rodlet configuration of the outer conidial layer.

Saprotrophic fungi Molds species that obtain nourishment by decomposing organic matter, such as dead plants or animals.

Secondary metabolites Organic compounds produced by microorganism metabolism which are not essential for normal growth but can provide advantages for the survival of microbial species.

Siderophore A high-affinity iron-chelating molecule that is secreted by many bacterial and fungal species.

Virulence Ability to infect and degree of damage caused by an organism.

Introduction

Aspergillus species are soil saprophytic molds found ubiquitously worldwide and are associated with decomposing organic biomass playing an important role in carbon and nitrogen recycling in nature. These opportunistic fungi species released abundant conidia into the air, of which at least several hundred will be inhaled by humans every day (Latgé, 1999).

Species of the *Aspergillus* genus are the etiologic agent responsible for several human and animal diseases that are generally called aspergillosis. For most patients, the primary route of infection is the respiratory tract by inhalation of air-borne conidia. While immunocompetent individuals rarely suffer any adverse effect due to the efficient elimination by mucociliary clearance and the innate immune response by macrophages (Hohl and Feldmesser, 2007), in patients with pulmonary disorders, such as asthma or cystic fibrosis, *Aspergillus* can cause allergic bronchopulmonary aspergillosis, and in high-risk immunocompromised individuals, the infection can lead to invasive aspergillosis (Dagenais and Keller, 2009). Apart from the respiratory tract, other sites of infection have been described but are much less common, such as the skin, peritoneum, kidneys, bones, eyes and gastrointestinal tract (Anaissie and Costa, 2001; Latgé, 1999; Walsh, 1998).

Aspergillosis comprises a variety of clinical manifestations. There are several factors that contribute to aspergillosis, including both fungus and host-related factors such as strain virulence and host pulmonary structure and immune status (Almyroudis *et al.*, 2005; Denning, 1998; Latgé, 1999; Singh and Bhalodiya, 2005) (Fig. 1). According to the host immunity, clinical presentations of aspergillosis range from asymptomatic colonization, superficial or saprophytic infection, allergy, and acute invasive disease (Latgé, 1999; Walsh *et al.*, 2008). Generally, allergic diseases are caused by a chronic response to mold colonization due to a repeated exposure to *Aspergillus* conidia or antigens, while superficial infections are related to local trauma or fungal overgrowth. In contrast, diseases which involve mycelial growth are more severe, such as allergic bronchopulmonary aspergillosis (ABPA), aspergilloma and invasive aspergillosis (IA) (Latgé, 1999). The last one is a systemic infection that has emerged as the leading cause of morbidity and mortality in immunocompromised hosts (Brown *et al.*, 2012; Denning, 1998). The immunocompromised populations that are most susceptible to invasive aspergillosis include patients with leukemia or genetic immunodeficiency diseases and patients undergoing bone marrow, hematopoietic stem cell, or solid-organ transplants. Mortality rates in these patients can reach up to 90% (Brown *et al.*, 2012; Kontoyiannis *et al.*, 2010; Pappas *et al.*, 2010). Furthermore, during the past few years, it has been increasing evidence for a genetic component that may render individuals more vulnerable to develop aspergillosis diseases (Maskarinec *et al.*, 2016).

Among the *Aspergillus* genus, *A. fumigatus* is the primary and most predominant human-pathogenic species and therefore the most common cause of aspergillosis (Kontoyiannis *et al.*, 2010; Pappas *et al.*, 2010). Besides *A. fumigatus*, there are other species of

Fig. 1 Schematic view of host and fungal factors contributing to *Aspergillus fumigatus* infections.

this genus that cause human infections, such as, *A. flavus*, *A. terreus*, *A. niger*, *A. tubingensis*, in order of frequency, among many others (Alastruey-Izquierdo *et al.*, 2013).

Currently, the treatment options for aspergillosis are limited to three classes of antifungal drugs that target essential structural components of fungal cells. Azoles and polyenes are aimed at ergosterol, the predominant sterol within the fungal cell plasma membrane, while echinocandins represent the newest class of antifungals and interfere with the fungal cell wall.

Despite the availability of drugs to treat *A. fumigatus* infections, therapy can be challenging for many patients. The reasons for that are associated to the diagnosis difficulties, the late initiation of antifungal therapy, the modest efficacy of existing antifungals and host toxicity. Altogether, they contribute to treatment failure and persistence of the fungus in the human host (Verweij *et al.*, 2016b). Furthermore, *A. fumigatus* azole resistance has emerged as a global health problem and although the amount of aspergillosis caused by azole-resistant isolates is still limited, different resistance mechanisms are arising (Verweij *et al.*, 2016a). Two routes of azole resistance development have been described; acquired during azole treatment and through an environmental exposure due to the use of these compounds as fungicides (Warris, 2015). The percentage of resistance prevalence varies between studies, but some authors reported an overall resistance rate of 5.7% among *A. fumigatus* isolates (Vermeulen *et al.*, 2015). Failing to control antifungal drug resistance, the scientific community has been encouraged to look for novel antifungals compounds which aim to target virulence determinants in *A. fumigatus*.

In this chapter, first we will describe the types of diseases caused by *A. fumigatus* and its symptoms according to the site of infection and the host health condition. Secondly, the molecular bases of *A. fumigatus* pathogenesis are discussed.

Clinical Manifestations of *Aspergillus fumigatus* Infections

Allergic Bronchopulmonary Aspergillosis (ABPA)

ABPA is a chronic allergic pulmonary disorder caused by hypersensitivity to *Aspergillus* species in response to colonization with the mold (Agarwal, 2009; Agarwal *et al.*, 2013). It is a very difficult syndrome to diagnose, but the classic criteria are chronic asthma, peripheral eosinophilia, skin test reactivity to *Aspergillus* antigen, precipitating *Aspergillus* antibodies, immunoglobulin E elevated in serum, recurrent pulmonary infiltrates, and central bronchiectasis (Agarwal, 2009; Agarwal *et al.*, 2013).

The clinical features are similar to asthma symptoms, including mostly wheezing, bronchial hyperreactivity, hemoptysis, productive cough with brownish black expectoration, and low-grade fever (Agarwal, 2009). Unfortunately, symptoms are not a good guide to predict outcome, as several asymptomatic patients developed eosinophilia and lung consolidation that resulted in chronic lung damage (Stevens *et al.*, 2000).

The prevalence of ABPA is reported to be up to 14% in patients with steroid- dependent asthma (Agarwal, 2009) and between 2% and 15% in patients with cystic fibrosis (CF) (Greenberger, 2003).

Allergic *Aspergillus* Sinusitis

Allergic *Aspergillus* sinusitis is a non-invasive inflammatory sinusitis caused by an allergic response to a local *A. fumigatus* infection (Singh and Bhalodiya, 2005). It is similar to any sinusitis but complicated with *Aspergillus* fungal balls (DeShazo *et al.*, 1997). Management of this infection consists in confirming lack of invasive infection and then treatment centers on aerating the sinus by endoscopic removal of debris and hyperplastic tissue (Schubert, 2004). The symptoms of an allergic *Aspergillus* sinusitis include stuffiness, runny nose, headache, and reduced ability to smell (Singh and Bhalodiya, 2005).

Typically, patients are young (near 30s) and present atopy, nasal polyps, and hypertrophic sinus disease (Schubert, 2004). Unfortunately, the use of antifungal agents or corticosteroids has not been conclusively demonstrated (Walsh *et al.*, 2008).

Aspergilloma

Aspergilloma, also called fungus ball, can be defined as a dense conglomeration of *Aspergillus* hyphae together with fibrin, mucus and cellular debris, within a pulmonary cavity or ectatic bronchus (Fraser *et al.*, 1998), and sometimes may also develop in other body sites, such as maxillary or ethmoid sinus or even in the jaw (Ferguson, 2000). Typically, these fungus balls develop in cavities as a result of pre-existing infections, such as tuberculosis, histoplasmosis, sarcoidosis, or other bullous lung disorders, and in chronically obstructed paranasal sinuses. Fungus balls are separated from the wall of the cavity by an airspace (Latgé, 1999; Stevens *et al.*, 2000).

The diagnosis of aspergilloma is based on chest radiographic features and serum precipitins positive to *Aspergillus* species (Lee *et al.*, 2004; Stevens *et al.*, 2000). Aspergillomas appear on chest radiographs as spherical masses surrounded by a radiolucent crescent (Broderick *et al.*, 1996). Although aspergilloma may be relatively asymptomatic and it usually does not spread to other parts of the body, invasive pulmonary aspergillosis may develop in some patients with aspergilloma.

Hemoptysis is a common clinical symptom of aspergilloma and can lead to fatal asphyxiation. It results from the disruption of blood vessels in the own cavity wall occupied by the fungus or in the bronchial artery supply far away from the aspergilloma (Latgé, 1999). Hemoptysis is the cause of death in up to 26% of patients with aspergilloma (Kauffman, 1996). Other symptoms are cough and shortness of breath.

Chronic Pulmonary Aspergillosis

Chronic pulmonary aspergillosis (CPA) is a progressive, debilitating infection, which progresses slowly, and by convention has to be present at least 3 months before diagnosis (Denning *et al.*, 2003). In this condition, imaging reveals one or more cavities in the lungs, with or without aspergilloma or with solid or cavitating nodules (Muldoon *et al.*, 2016). In addition, pleural thickening is characteristic of CPA but not universal (Denning *et al.*, 2011).

Pulmonary symptoms are productive cough, hemoptysis, chest discomfort and shortness of breath. Also fatigue and weight loss are common features of this disorder (Al-shair *et al.*, 2013).

About 3 million people worldwide have CPA, of whom 1.2 million have previously had pulmonary tuberculosis, therefore they have a history of lung defects but they are not immunocompromised patients (Denning *et al.*, 2011; Smith and Denning, 2011).

Invasive Aspergillosis

Invasive aspergillosis (IA) has become an important cause of death, mainly among hematological patients, such as patients with neutropenia or neutrophil and/or macrophage disorders, also patients exposed to cytotoxic chemotherapy, long-term corticosteroid treatment, bone marrow or organ transplant, or with any immunodeficiency, congenital or acquired (Stevens *et al.*, 2000).

Normally, inhaled airborne conidia invade the lung tissue thanks to the lack of an effective immune response. Afterwards, hyphal invasion into blood vessels is common, which leads to infection of pulmonary or non-pulmonary sites by contiguous or hematogenous spread to the central nervous system or to other organs.

Invasive pulmonary aspergillosis

The main clinical presentation of IA is invasive pulmonary aspergillosis (IPA), which rarely manifests before 10–12 days of profound neutropenia (Patterson, 2011).

As other forms of aspergillosis, the general symptoms of IPA are fever despite therapy with broad-spectrum antibiotics, chest pain, dry cough, dyspnea, and weight loss. Other manifestations include hemoptysis and pneumothorax (Latgé, 1999; Patterson, 2011). Also, when patients develop more severe pulmonary involvement, respiratory failure, hypoxemia with compensatory hyperventilation, hypo apnea, and respiratory alkalosis are characteristic (Patterson, 2011). Other symptoms can develop if the infection spreads from the lungs to other parts of the body.

Since IPA is a devastating infection which progresses very fast and is difficult to diagnose, clinicians often treat the patient empirically before confirming the final diagnosis in order to avoid a greater risk of untreatable IPA due to a too high level of fungal burden (Latgé, 1999). Therefore, a prompt antifungal therapy may be essential for patient survival.

Fig. 2 Morphological stages of *Aspergillus fumigatus* during *in vitro* growth: (A) resting conidia, (B) swollen conidia, (C) starting to germinate conidia, (D) germ tubes, (E) hyphae.

Other aspergillosis invasive syndromes

Non-pulmonary organs, such as the liver, spleen, kidney, skin, bone or heart, can be infected through fungus dissemination towards nearby locations, simply for closeness, or by the own bloodstream (Patterson, 2011). This may result in different invasive infections.

Sinusitis is a relatively common manifestation of IA, developing as an isolated syndrome or within an IPA context. In the case of tracheobronchitis, it is common to develop in AIDS or lung transplantation patients.

Cutaneous aspergillosis can occur as a disseminated hematogenous spread from a primary focus of infection, most often the lungs, in neutropenic or highly immunocompromised patients, or as a local infection associated with intravenous catheter insertion or adhesive dressings for venous access devices contaminated with the fungus (Walsh *et al.*, 2008). The lesions can be single or multiple, most commonly on the extremities, firstly appear as erythematous papules, then become pustular, and subsequently necrotic with a central ulceration and an elevated border covered by a black eschar (Stevens *et al.*, 2000).

Finally, one of the most severe complications is cerebral aspergillosis, which is associated with disseminated disease. It presents very high mortality rates and occurs in 10%–20% of all IA cases (Patterson, 2011).

Molecular Bases of *Aspergillus fumigatus* Virulence

Pathogenicity can be defined as the capacity of a microbe to cause damage in a host while virulence refers to the degree of damage caused by the microbe (Casadevall and Pirofski, 1999). In line, host damage can occur as a result of direct microbial action on tissues, as a result of the immune response to the microbe, or a combination of both. A virulence factor is the microbial component that damages the host (Casadevall and Pirofski, 1999).

Among the 185 species belonging to the genus *Aspergillus*, only a fractional proportion of them are pathogenic for humans. What distinguishes more virulent organisms, such as *A. fumigatus*, from more benign species has been an important research area for many years. In the absence of unique molecules or pathways that have an essential impact on *A. fumigatus* survival it has been assumed that its virulence is multifactorial.

A. fumigatus has one of the fastest growth rates among species of the fungal kingdom that promotes their colonization of multiple niches (van de Veerdonk *et al.*, 2017). The life cycle of *A. fumigatus* involves several distinct morphogenetic transitions. These transitions include the formation of conidial spores through conidiation, the conidial germination, and polarized hyphal growth. These morphogenetic changes can be microscopically observed when *A. fumigatus* is growing in *in vitro* conditions (Fig. 2). In a similar manner when conidial spores interact with a susceptible host, they would experience the same morphological transitions until they reach hyphal growth (Fig. 3).

According to the life cycle, *A. fumigatus* virulence traits are linked to fungal structures, morphological changes during developmental growth, metabolic requirements that change in order to adapt to the host environment and mechanisms to escape from the host immune responses. These adjustments are classified according to the process in which they are involved, and are described below:

A. fumigatus produces conidia (asexual spores) which are one of the first important pathogenic traits to consider. When comparing to other *Aspergillus* species, such as *A. flavus* or *A. niger*, *A. fumigatus* spores are smaller and much more hydrophobic so they can disperse more quickly in the environment. Altogether, these features facilitate that *A. fumigatus* spores enter easily into the respiratory tract, reaching the human alveoli (Kwon-Chung and Sugui, 2013).

As other human pathogens, *A. fumigatus* grows well at 37°C but it is more resistant than other fungi to changes in temperature, as it can tolerate temperatures ranging from 37 to 50°C (Bhabhra and Askew, 2005; Sales-Campos *et al.*, 2013). The ribosomal biogenesis proteins encoded by *crGA* (Bhabhra *et al.*, 2004), α -mannosyltransferase (*kre2/mnt1*) (Wagener *et al.*, 2008), and the endoplasmic reticulum-transmembrane sensor encoded by *ireA* (Feng *et al.*, 2011) are, up to date, the known proteins associated with thermotolerance growth and hypovirulence, when the respective genes were deleted from *A. fumigatus* genome.

The surface of *A. fumigatus* conidia is covered by a thin layer called rodlet layer composed by regularly arranged hydrophobic proteins (hydrophobins) that are covalently bound to the cell wall. This layer contributes to conidial dispersion and soil fixation, but it also prevents conidia from the immune response by masking its recognition (Aimanianda *et al.*, 2009). *A. fumigatus* contains two hydrophobins: RodAp, encoded by the RODA gene, and RodBp, encoded by the RODB gene. Using single and double

Fig. 3 Histological sections of murine lungs infected with *Aspergillus fumigatus*: (A) Recruitment of immune cells and inflammatory response at the site of infection, (B) In black *A. fumigatus* hyphae can be observed in the murine lung.

mutants it has been shown that RodBp is not involved in rodlet formation neither protects against conidial killing by alveolar macrophages (Aimanianda *et al.*, 2009).

A. fumigatus conidia are grey-green due to the pigment DHN-melanin. The role of melanin has been studied by using pigmentless mutants showing that melanin protects against enzymatic lysis and environmental stress, such as UV light and oxidizing agents. Altogether, these functions contribute to attenuate the host immune response and to promote *A. fumigatus* dissemination (Bayry *et al.*, 2014). As an alternative to melanin, *A. fumigatus* produces a brownish pigment called pyomelanin (Schmaler-Ripcke *et al.*, 2009). Pyomelanin is synthesized via tyrosine degradation pathway and is involved in preserving fungal survival by protecting from host immune defense mechanisms during infection (Keller *et al.*, 2011).

A. fumigatus cell wall represents the first point of contact with the host, playing an important role in pathogenesis. The cell wall is a physical structure that provides protection to the fungal cell and is one of the main targets for antifungal agents. During the life cycle of *A. fumigatus*, the cell wall composition changes continuously with cell cycle progression and in response to environmental changes. The cell wall is mainly composed by polysaccharides: (1,3) glucans, (1,3)/(1,4) glucans, (1,6) glucans, chitins, galactomannans and galactosaminogalactans (Fontaine *et al.*, 2000). The cell wall synthesis can be an example of gene function redundancy found in the *A. fumigatus* genome. For instance the cell wall (1,3) glucan polysaccharide is synthesized by three (1,3) glucan synthases. The three corresponding glucan synthase genes (*ags1*, *ags2*, and *ags3*) have been deleted from the genome. While the *ags1* mutant displayed the most profound glucan synthetic deficit (Beauvais *et al.*, 2005), the *ags3* deleted mutant showed enhanced virulence in a murine model of IA (Maubon *et al.*, 2006). In addition, seven chitin synthases have been identified in *A. fumigatus* genome (Mellado *et al.*, 1995). Four genes among them were assessed for virulence profile and only the *chsG* null mutant strain displayed a hypovirulence phenotype (Mellado *et al.*, 1996a,b).

The conidial cell wall also has galactose-containing polysaccharides such as galactomannan (GM) and galactosaminogalactan (GAG) (Gresnigt *et al.*, 2014). GMs are composed by a linear mannan backbone and short chains of (1,5) galactofuranose residues. Galactofuranose biosynthesis starts with the isomerization of UDP galactopyranose to UDP galactofuranose by UDP galactomutase encoded by the *glfA* gene. The absence of UDP galactomutase in *A. fumigatus* led to attenuated virulence in a mouse model of IA. GMs are released during tissue invasion which may activate the innate immune response away from the focus of infection. In addition, GMs are exoantigens and, in fact, are used in commercial kits for the diagnosis of IA (Wheat and Walsh, 2008). GAGs are expressed during conidial germination and hyphal growth and have possible anti-inflammatory effects. GAG induces the anti-inflammatory cytokine interleukin-1 receptor antagonist, turning individuals more susceptible to aspergillosis (Gresnigt *et al.*, 2014).

A. fumigatus cell wall contains at least nine glycosylphosphatidylinositol (GPI) linked proteins connected to the polysaccharide skeleton (Bruneau *et al.*, 2001). These proteins play important roles in the biosynthesis and organization of the fungal cell wall because many proteins, such as cell surface enzymes, receptors, and adhesion molecules, are anchored to the cell membrane by the GPI anchor which in turn may transfer the cell-wall-related information across the cell membrane. In this context, the absence of glucanosyltransferase encoded by *gel2* gene has been related to hypovirulence of *A. fumigatus* (Mouyna *et al.*, 2005). Another gene related to virulence attenuation in *A. fumigatus* is *Afpig-a*, which encodes the catalytic subunit of a complex that is responsible for GPI anchor biosynthesis (Li *et al.*, 2007). On the other hand, *ecm33* gene which encodes a GPI-anchored protein, plays an important role in maintaining fungal cell wall integrity, and the absence of this enzyme enhances the virulence of the fungus. Although Δ *ecm33* conidia are more resistant to be killed by alveolar macrophages and neutrophils than control cells, Δ *ecm33* hyphae are more susceptible to neutrophil-dependent killing (Romano *et al.*, 2006; Chabane *et al.*, 2006).

A. fumigatus secretes numerous secondary metabolites which are specially produced during mycelial growth. These secreted products are important for *A. fumigatus* pathogenicity and include mycotoxins, and enzymes such as proteases, catalases, and

phospholipases. Mycotoxins are also produced by different fungal species, can be toxic for both human and animals and are able to cause disease and death. In *A. fumigatus*, five mycotoxins have been identified: gliotoxin, fumagillin, helvolic acid, fumitremorgin A and Asp-hemolysin (Kamei and Watanabe, 2005; Dagenais and Keller, 2009). Gliotoxin is a member of the epipolythiodioxopiperazine class of toxins. It is the most abundantly produced by *A. fumigatus* and due to its relevance in virulence it is the most studied. Gliotoxin can be also detected in human samples from patients with aspergillosis (Lewis *et al.*, 2005) so a special effort has been given in order to use this molecule for diagnostic purposes. Gliotoxin has immunosuppressive properties and modulates the immune response, affects circulating neutrophils, suppresses reactive oxygen species (ROS) production and inhibits phagocytosis of conidia (Scharf *et al.*, 2012). Mutants unable to produce gliotoxin have a dual phenotype in murine models of aspergillosis. While virulence is not affected in a neutropenic model of aspergillosis, it is reduced in a corticosteroid model of infection (Spikes *et al.*, 2008; Sugui *et al.*, 2007). As other secondary metabolites, genes required for gliotoxin biosynthesis are found in clusters in the genome. The gene *laeA* encodes a transcription factor which is a global regulator of these secondary metabolite clusters in *A. fumigatus* (Perrin *et al.*, 2007). The deletion of *laeA* in this fungus reduces the secondary metabolite production, including gliotoxin, and reduces the virulence in a neutropenic murine model.

A. fumigatus secretes proteolytic enzymes such as serine, metallo and aspartic proteases (Bergmann *et al.*, 2009). Although these enzymes are necessary for fungal growth in plants, they appear to be relevant as virulence factors also for its filamentous growth in the mammalian host, as require the breakdown of host tissue for nutrient acquisition and invasion (de Vries and Visser, 2001). This happens in enzymes with elastinolytic activity that acts degrading structural barriers of host tissues. Elastin constitutes nearly 30% of lung tissue and elastinolytic activity has been described to be implicated in the pathogenesis of *Aspergillus* (Blanco *et al.*, 2002; Binder and Lass-Flörl, 2013).

A. fumigatus is able to adapt in response to low nutrient availability in the host and to uptake what it needs to grow from the site of the infection. Among nutrients, the *in vivo* environment iron is essential to begin the infection. To regulate iron availability (iron uptake and iron storage), *A. fumigatus* uses low-molecular mass iron-specific chelators called siderophores. Siderophores are central components of the fungal metabolism as they affect germination, sexual and asexual reproduction, and oxidative stress resistance. In addition, *A. fumigatus* can acquire iron by reductive iron assimilation. While the later mechanism is not essential for *A. fumigatus* virulence, inactivation of siderophore biosynthesis reduces its virulence. Iron also influences processes such as ergosterol biosynthesis, azole drug resistance, hypoxia adaptation, and the interaction with the host immune cells (Haas, 2014).

The iron availability in eukaryotes and cellular response to low oxygen are intimately related (Sales-Campos, 2013). In an infection, *A. fumigatus* is exposed to active changes in the oxygen concentration; in fact the quantity of oxygen at the site of infection is low due to the inflammatory process. The sterol regulatory element-binding protein, SrbA, is critical for coordinating genes involved in iron acquisition and ergosterol biosynthesis under hypoxia (Willger *et al.*, 2008). The *srbA* null mutant is unable of growing in a hypoxic environment and consequently is unsuccessful to cause disease in a murine model of IPA (Willger *et al.*, 2008). In addition, mitochondrial respiration is active during hypoxia. The deletion of the cytochrome C (*cycA*) which is involved in mitochondrial respiration in *A. fumigatus* led to significant impaired conidia germination, and mutant strains displayed attenuated virulence in murine model of IPA (Grahl *et al.*, 2012).

Availability of low levels of zinc can restrict the growth of pathogens. In *A. fumigatus* the transcriptional activator ZafA regulates zinc homeostasis and is essential for its pathogenicity and virulence. The *zafA* null mutant is avirulent in cortisone acetate-immunosuppressed mice (Moreno *et al.*, 2007). Zinc is also essential for a wide variety of biochemical processes in fungi, for the adequate regulation of gene expression and thus for cellular growth and development. A clear relationship has been shown between zinc homeostasis and virulence of *A. fumigatus*, which requires the zinc transporters ZrfA, ZrfB and ZrfC for growing within the host (Amich and Calera, 2014; Moreno *et al.*, 2007).

Essential metabolic pathways that inhibit fungal metabolism during pathogenesis are also interesting. Fungal species as well as other microorganisms have developed specific pathways for the biosynthesis of all proteinogenic amino acids (Jastrzebowska and Gabriel, 2015). Among the 20 amino acids, nine are essential for humans and therefore several steps of the amino acid biosynthetic pathways are catalyzed by enzymes that are absent in mammals. In *A. fumigatus*, it is known that some biosynthetic pathways of amino acids are crucial determinants for its virulence. For instance, biosynthesis of lysine (Liebmann *et al.*, 2004a,b; Schobel *et al.*, 2010), aromatic amino acids (Schobel *et al.*, 2010), and sulfur-containing amino acids such as methionine and cysteine (Amich *et al.*, 2016), have been evaluated for their role in *A. fumigatus* pathogenesis.

Synthesis of histidine in *A. fumigatus* is encoded by seven genes of which the *hisB* was deleted ($\Delta hisB$) (Dietl *et al.*, 2016). Deletion of this gene function in *A. fumigatus* caused histidine auxotrophy. Further analysis of histidine requirement *in vivo* was performed by testing the pathogenicity of $\Delta hisB$ strain in different models of *A. fumigatus* infection: murine pulmonary infection, murine systemic infection, murine keratitis and the wax moth larvae *Galleria mellonella*. The $\Delta hisB$ strain showed reduced virulence in all murine models (Dietl *et al.*, 2016).

Resistance to oxidative stress. The NADPH oxidase complex produces reactive oxygen species (ROS) in macrophages and polymorphonuclear cells such as neutrophils, and regulates several crucial pathways in host defense against *A. fumigatus*. To fight against these mechanisms, *A. fumigatus* produces specific enzymes for ROS detoxification. ROS detoxification proteins are classified in different categories, of which the catalases peroxidases, Cat1/CatB and Cat2/KatG, are produced by the fungus mycelia. The null mutant of each gene in *A. fumigatus* led to mycelial hydrogen peroxide sensitivity and virulence reduction in the lungs of immunosuppressed rats (Paris *et al.*, 2003; Calera *et al.*, 1997). Another group of genes related to oxidative stress response are the fatty acid oxygenases *ppoA*, *ppoB*, and *ppoC*, which are similar in sequence to specific mammalian prostaglandin synthases, the cyclooxygenases. The *A. fumigatus* fatty acid oxygenases encoding by these genes were tested for virulence, so the triple mutant

strain was produced and it was found to be hypervirulent in an invasive murine model, showing increased tolerance to hydrogen peroxide (Tsitsigiannis *et al.*, 2005).

Another mechanism linked to virulence is the production of biofilms. *A. fumigatus* can grow as a colony characterized by multicellular and multilayered hyphae which are embedded in an extracellular matrix (ECM) defined as biofilms (Loussert *et al.*, 2010). Biofilm growth can be observed in human lung aspergilloma and mice lungs infected with *A. fumigatus*. Composition analysis of *Aspergillus* biofilms *in vivo* shows that the ECM of both lungs contained the polysaccharides GM and GAG. Interestingly, α 1,3 glucan polysaccharides and melanin were detected in the ECM of aspergilloma biofilms, while in invasive forms of aspergillosis, the α 1,3 glucans were only found in the inner layer of the hyphal cell wall, and melanin could not be determined (Loussert *et al.*, 2010). The MedA protein has been described to be involved in biofilm formation as the Δ medA mutant is impaired in biofilm production and adherence to plastic, as well as in adherence to pulmonary epithelial cells, endothelial cells and fibronectin *in vitro*. Consistent with these results, the Δ medA strain has reduced virulence in both an invertebrate and a mammalian model of IA as well as reduced capacity to damage pulmonary epithelial cells and stimulate a cytokine response (Gravelat *et al.*, 2010).

In addition, *A. fumigatus* biofilms are more resistant to the antifungal drugs polyenes, azoles, and echinocandins and are reservoirs for microorganisms that may become potential sources of infection for susceptible patients (Beauvais and Latgé, 2015).

A significant relationship exists between *A. fumigatus* morphogenesis and pathogenicity. Proteins that participate in the signal transduction such as the G- proteins, MAP kinases, adenylate cyclases, and protein kinases (PKA) have been associated with virulence control and development of fungal pathogens (Lengeler *et al.*, 2000). Among them, the cAMP-PKA pathway is the best-characterized signaling cascade and is involved in regulating *A. fumigatus* morphogenesis. In this species, the pathway includes a regulatory heterotrimeric G protein (*gpaB*), an adenylate cyclase (*acyA*), and the regulatory (*pkaR*) and catalytic (*pkaC1*) subunits of PKA (Hohl and Feldmesser, 2007). The malfunction of proteins involved in the cAMP-PKA pathway results in altered germination as well as decreased virulence in murine models (Liebmman *et al.*, 2004a,b; Zhao *et al.*, 2006).

Other signal transduction pathways in fungi involve calcium. Calcium can enter fungal cells in response to external stress and activates the calcium-binding protein calmodulin that in turn activates calcineurin (Sales-Campos *et al.*, 2013). The calcineurin pathway mediates growth, morphology, stress response pathways including survival in the host environment and resistance to antifungal drugs (Kraus and Heitman, 2003). The deletion of the catalytic subunit of calcineurin, *calA/cnaA* as well as the downstream effector of calcineurin, *crzA*, in *A. fumigatus*, led to significant defects in conidial germination, hyphal morphology, decreased filamentation, impaired cell wall structure, and virulence attenuation in an experimental neutropenic inhalational murine model of IPA (Cramer *et al.*, 2008; Sales-Campos *et al.*, 2013; Steinbach *et al.*, 2007).

Together with calcineurin, Ras proteins are also involved in the regulation of hyphal and cell wall formation (Sales-Campos *et al.*, 2013). Ras proteins are small monomeric GTPases that transduce signals from outside of the cell to signal pathways inside the cell. The deletion of these Ras proteins encoding genes, Δ rasA, Δ rasB, and Δ rhbA leads to *A. fumigatus* decreased virulence in an IPA murine model (Sales-Campos *et al.*, 2013).

Conclusions

A. fumigatus is ubiquitous in the environment. It is found in soil, decaying vegetation compost and most indoor environments. It also interacts with diverse animal hosts and dominates among microbial communities. In addition, compare to other fungal species even from the same genus, it has an exceptional capacity to reach, develop and invade the human body. *A. fumigatus* is an opportunistic pathogen causing a wide range of infections in humans. Clinical manifestations of aspergillosis are determined by the host's immune response against the fungi and have been classically divided into superficial infections, allergic forms when there is an exaggerated response of the immune system to *Aspergillus* colonization of the airways, and invasive aspergillosis, a systemic infection that affects immunosuppressed patients.

After many years of research, a growing number of virulence factors favoring the pathological process has been continuously described. *A. fumigatus* virulence depends on multiple factors associated to the cell structure, morphogenetic reprogramming, stress response, secretion of enzymes and secondary metabolites, nutrient acquisition and synthesis, and adaptation to host conditions that includes escaping from the immune system.

For the near future, using novel approaches based on whole-genome analysis such as genome sequencing comparison between *A. fumigatus* strains or between different *Aspergillus* species, as well as whole transcriptomics of the fungus growing in host conditions, promise to fuel our understanding of the highly complex nature of *A. fumigatus* pathogenesis and clinical outcomes.

Introduction

Fungi of the order Mucorales represent a ubiquitous part of the environment, thriving on wet organic materials to cause rot and spoilage. Mucorales fungi are also widely used in food production through their ability to secrete a variety of enzymes (e.g., amylase, lipase and protease), used in fermentation, and production of cheese and soy products (e.g., Tempeh) (Morin-Sardin *et al.*, 2017). The ability to secrete enzymes are also used in the development of several medically and pharmaceutically important compounds such as steroids and terpenoids (Morin-Sardin *et al.*, 2017). In contrast, several species of these thermotolerant/philic Mucorales can cause mucormycosis, a life-threatening infection that mostly occurs in patients with impaired immunity (Ribes *et al.*, 2000; Spellberg *et al.*, 2012; Roden *et al.*, 2005). Humans are frequently exposed to Mucorales spores via inhalation, ingestion or direct inoculation into an abraded skin or an open wound. The genera most commonly implicated in human infections are *Rhizopus*, *Mucor*, *Rhizomucor*, *Lichtheimia*, *Cunninghamella*, *Saksenaea*, and *Apophysomyces*. This review focuses on the medically important Mucorales, elaborating on recent advances in epidemiology, pathophysiology, pathogenesis and molecular diagnosis of mucormycosis. We also present recent treatment strategies and research endeavors to counter the expanding global problem of mucormycosis.

Epidemiology and Burden of Disease

A total of 11 genera and ~27 species under the order Mucorales are known to cause mucormycosis. Amongst these, *Rhizopus*, *Lichtheimia* and *Mucor* represent the most common agents associated with human disease (Jeong *et al.*, 2019).

Rhizopus spp. is frequently associated with the rhinoorbital/cerebral form of the disease, *Cunninghamella* spp. with pulmonary or disseminated disease, while *Apophysomyces* and *Saksenaea* spp. are reportedly isolated from cutaneous mucormycosis (Jeong *et al.*, 2019). Diabetes and ketoacidosis are the primary causes of rhinoorbital/cerebral mucormycosis, whereas corticosteroid usage promotes infection by *Lichtheimia* spp. (Lanternier *et al.*, (2005–2007)). Of all agents of mucormycosis, *Cunninghamella* spp. causes the highest rate of mortality with ~70% lethality versus ~50% rate of all-cause mortality (Roden *et al.*, 2005; Jeong *et al.*, 2019).

Rhizopus spp. remain the most common cause of mucormycosis with ~ half of the cases seen world-wide attributed to this genus (Jeong *et al.*, 2019). The second most common isolate appears to be geographically-dependent with *Mucor*, *Lichtheimia*, and *Apophysomyces* reported as the second most common in the Americas, Europe and the Indian subcontinent, respectively (Skiada *et al.*, 2018; Nucci *et al.*, 2019; Prakash and Chakrabarti, 2019). Although the worldwide incidence of mucormycosis is difficult to estimate, as it is not a reportable disease, recent data show a striking increase in the number of reported cases of mucormycosis (Gleissner *et al.*, 2004). There has been an alarming rise in the incidence of mucormycosis at major US transplant centers. The number of cases over a 15 year period has more than doubled (Marr *et al.*, 2002; Kontoyiannis *et al.*, 2000). Prevalence rates are up to 8% in autopsied patients with leukemia (Greenberg *et al.*, 2004). A French study showed a 70% increase in mucormycosis cases between 1997 and 2006 (Bitar *et al.*, 2009). The highest incidents of mucormycosis are reported in India, with ~200,000 cases/year (Patel *et al.*, 2017; Bala *et al.*, 2015; Chakrabarti and Singh, 2014). In a more recent retrospective study in the United States using the Premier Perspective™ Comparative Database, with more than 560 participating USA hospitals covering 104 million patients, found the prevalence of mucormycosis-related hospitalizations at 0.12 per 10,000 discharges (Kontoyiannis *et al.*, 2016). Readmission rates were high in this study, with 30% and 37% of patients readmitted within one and three months of discharge, respectively, and the median length of stay was 17 days, with 23% deceased at discharge. The average cost per hospital stay was a staggering: \$112,419 (Skiada *et al.*, 2018).

Leading International Fungal Education (LIFE) portal has estimated the global burden of mucormycosis to be ~10,000 cases per year barring the incidents from India. A review of 929 reports published between the years 1885 and 2004 revealed that the common risk factors for mucormycosis were diabetes mellitus (36%), followed by hematologic malignancies (17%) and solid organ or hematopoietic cell transplantations (12%). The majority of patients with malignancy suffered from pulmonary disease, whereas patients with diabetes were afflicted primarily with rhinoorbital/cerebral disease. However, more recent data from developed countries have reported an increase in mucormycosis in hematologic malignancies, especially in patients with graft versus host disease and patients receiving hematopoietic cell transplants (Marr *et al.*, 2002; Bitar *et al.*, 2009; Trifilio *et al.*, 2007; Kontoyiannis *et al.*, 2005; Kauffman and Malani, 2007). A number of factors have promoted the rise in the number of malignancy-related mucormycosis cases including; (1) use of antifungals such as voriconazole or echinocandins that are inactive against Mucorales; (2) severe defects in immune-competency due to use of immunosuppressive agents; (3) a decrease in aspergillosis-related mortality, resulting in the emergence of less common invasive mold infections during the late post-transplant period (Pagano *et al.*, 2009; Nucci and Marr, 2005; Marr *et al.*, 2009); and (4) frequent blood transfusions leading to increased serum

Fig. 1 Morphology of *Rhizopus delemar*. Sporangia form at the apices of sporangiophores and contain the asexual sporangiospores. Columella is a sterile dome shaped structure found at the tip of sporangiophore. Scale bars, 30 μ m.

iron levels, a metal that supports the growth of Mucorales fungi (Ibrahim, 2011; Ibrahim *et al.*, 2005b; 2008b). Moreover, a change in epidemiology of mucormycosis has been noted in recent years with emergence of new risk factors and causative agents, worldwide. This is largely driven by advances in molecular diagnostics, and geoclimatic factors influencing causative agents (McCarthy *et al.*, 2017). Post-tuberculosis, chronic renal failure and stay in the intensive care unit are new risk factors for the disease especially in developing countries. *Rhizopus homothallicus*, *Thamnostylum lucknowense*, and *Mucor irregularis* are the newly emerging species (Prakash and Chakrabarti, 2019). This shifting epidemiology warrants an increased need for global reporting and ongoing population-based studies categorized by risk (e.g., diabetes, malignancies) to broaden our understanding of the global burden of the disease.

Infection with Mucorales have also occurred as an aftermath of natural disasters such as tsunamis, tornados or volcanic eruptions (Green and Karras, 2012; Beaumont *et al.*, 1985; Patiño *et al.*, 1991; Neblett Fanfair *et al.*, 2012). For example, following a tornado in Joplin, Missouri, United States in 2011, 13 injured (yet otherwise immunocompetent) people developed necrotizing soft tissue infections by *Apophysomyces trapeziformis* (Green and Karras, 2012). Similar findings were reported following the South-Eastern Asian Tsunami (Andresen *et al.*, 2005). Presumably, the infection occurred after the fungus was introduced into breached skin due to wounds. A more prominent example of trauma-related infections are those reported in military personnel with combat injuries. Between June 2009 and through December 2010, a total of 37 confirmed cases were identified in soldiers who sustained blast injuries during combat in Afghanistan. These patients required frequent debridements or amputation revisions and resulted in a mortality rate of 8% (Warkentien *et al.*, 2012; Tribble and Rodriguez, 2014; Rodriguez *et al.*, 2014a,b; Weintrob *et al.*, 2015; Tribble *et al.*, 2015).

Pathogenesis and Host Immune Response

Mucoralean fungi reproduce both sexually and asexually. The asexual sporangiospores are present on the apex of a globular structure called the sporangium (Fig. 1). The sporangiospores can disperse post the disintegration of the sporangium wall, and germinate into hyphae. Most of the pathogenic Mucorales are heterothallic, and their sexual cycle initiates when hyphae of opposite mating types [(−) and (+)] undergo fusion to form zygospores, which later germinate to form a sporangium at the apex culminating in sexual meiospores (Lee *et al.*, 2010). Since the sexual life cycle for sporangiospore production is prolonged, it is anecdotally accepted that asexual sporangiospores may serve as the major source of dissemination and infection.

Rhinoorbital/cerebral and pulmonary mucormycosis, the two major disease forms, are acquired by inhalation of spores from the environment. In immunocompetent individuals, spores are transported to the pharynx and cleared through the gastrointestinal tract. To the contrary, in susceptible individuals, infection begins in the nasal cavity or lungs. Cutaneous mucormycosis represents the third most common manifestation of the disease and usually acquired either through severe trauma or direct inoculation into

abraded skin (Sugar, 2005; Ibrahim *et al.*, 2011). Agents of mucormycosis cause enhanced invasion and destruction of tissues, and are clinically considered to be the most angioinvasive of all of the fungal infections. Mucorales are the cause of the third most common invasive fungal infections among hematologic and allogeneic stem cell transplantation patients, trailing only candidiasis and aspergillosis (Petrikos *et al.*, 2012). In the case of rhinoorbital/cerebral involvement, the disease is manifested as orbital cellulitis, bone rarefaction, erosion of the skull base, cavernous sinus thrombosis, infarcts and intra-cranial abscess in the brain, culminating into enhanced facial necrosis and deformation. In pulmonary mucormycosis, the disease is characterized as lung infiltration (58%–96%), pleural effusion (6%–21%), thickly walled cavities (6%–37%), and lymphadenopathy (3.3%) (Sugar, 2005).

Nasal and lung epithelial cells are among the first host cells that encounter inhaled spores. To gain insight into the molecular mechanisms that govern Mucorales-host airway epithelial cell interactions, Watkins *et al.* (2018) employed transcriptome sequencing (RNA-seq) to monitor host transcriptional response during early stages of *R. delemar* infection in a murine model of pulmonary mucormycosis. Network analysis revealed activation of the host's epidermal growth factor receptor (EGFR) signaling. Further studies revealed that EGFR is activated by phosphorylation upon interaction with several genera of Mucorales, and colocalizes with *R. delemar* spores during invasion of alveolar epithelial cells. EGFR inhibitors cetuximab and gefitinib protected airway epithelial cells from invasion and damage by *R. delemar* *in vitro*. Furthermore, gefitinib significantly prolonged survival of mice with pulmonary mucormycosis, and reduced tissue fungal burden of target organs (Watkins *et al.*, 2018). These results present EGFR as a novel host receptor during invasion of alveolar epithelial cells by *R. delemar*. Importantly, this study shows that the use of the FDA9-approved drug, gefitinib, could prove to be beneficial in treating pulmonary mucormycosis as an adjunctive therapy.

Alveolar macrophages provide the first line of defense against inhaled Mucorales spores (Aberdein *et al.*, 2013; Ibrahim and Voelz, 2017). Studies have shown that macrophages from immunocompetent mice are efficient in taking up Mucorales spores and prevent their germination (Diamond *et al.*, 1982; Waldorf, 1989; Waldorf *et al.*, 1984a,b). However, spore uptake by these macrophages does not translate into cidal activity, since normal macrophages are inefficient at killing spores. To make matters worse, under diabetic conditions spore germination is enhanced in macrophages, leading to higher mortality in the diabetic mice (Waldorf *et al.*, 1984b). This outcome is in sharp contrast to *Aspergillus* conidia, which can be efficiently cleared by the immune system (Diamond *et al.*, 1982; Waldorf, 1989; Waldorf *et al.*, 1984a,b; Lee *et al.*, 2015). However, macrophages and monocytes can bind to, and damage Mucorales hyphae by release of oxygen radicals without ingesting the hyphae. Unraveling the less understood unique mechanism by which Mucorales persist in alveolar macrophages and resist killing is fundamental to identifying novel approaches to control the infection. In this respect, Andrianaki *et al.* (2018) found that lack of intracellular spore swelling inside alveolar macrophages results in surface retention of melanin. The retention of melanin induces phagosome maturation arrest through inhibition of LC3-associated phagocytosis resulting in persistence of spores within macrophages. On the other hand, studies using transcriptomic, iron-supplementation, and genetic manipulation of iron assimilation genes showed that iron restriction inside macrophages regulates immunity against *Rhizopus* and prevents germination of the fungus (Andrianaki *et al.*, 2018).

The resistance of Mucorales to innate immune cells also extends to neutrophils with hyperglycemia having a detrimental impact on chemotaxis and killing activity of these polymorphonuclear cells (Chinn and Diamond, 1982). Specifically, acidosis disrupts the ability of transferrin to efficiently chelate iron by a proton-mediated mechanism (Ibrahim *et al.*, 2008b; Artis *et al.*, 1982; Gebremariam *et al.*, 2016; Walsh *et al.*, 2012). The released iron is known to be toxic to phagocytes (Cantiniaux *et al.*, 1999; Guo *et al.*, 2002; Omara *et al.*, 1994) and spleen cells from mice fed excess levels of iron secrete less interferon-gamma (IFN- γ) (Omara and Blakley, 1994), a cytokine that upregulates killing of Mucorales fungi by human neutrophils (Gil-Lamaignere *et al.*, 2005). Implementation of IFN- γ and granulocyte-macrophage-colony-stimulating factor (GM-CSF) alone or in combination has been found to augment the ability of neutrophils to damage and kill Mucorales hyphae *ex vivo*, through augmentation of the oxidative burst and TNF- α release (Gil-Lamaignere *et al.*, 2005).

The role of adaptive immunity in mucormycosis patients has not been investigated extensively. Of note, similar to *Aspergillus*, β -glucan exposure during germination of *Rhizopus* triggers dectin-1 signaling in human dendritic cells and results in robust induction of the IL-23/Th-17 responses (Chamilos *et al.*, 2010). Interestingly, only patients with mucormycosis produce Mucorales-specific T-cells, which are adept at damaging hyphal cells (Potenza *et al.*, 2011; Schmidt *et al.*, 2012). In fact, T-cells pulsed with *Rhizopus* extract and activated with IL-2/IL-7 trigger the production of Mucorales-specific T cells that contain CD4⁺ (Castillo *et al.*, 2018). These cells are capable of producing IFN- γ , IL-5, IL-10, IL-13, and TNF- α and recognize fungal antigens presented by HLA-II molecules rather than through non-specific signaling (Castillo *et al.*, 2018).

Molecular Pathogenesis of Mucorales

A major impediment to the in-depth study of genes and signaling pathways of Mucorales fungi is the availability of only a limited set of tools for genetic manipulation. A whole-genome duplication occurred early in the Mucormycotina lineage and the duplication of genes may have provided new proteins thereby expanding the sensory and signaling pathways (Garcia *et al.*, 2018; Ma *et al.*, 2009; Schwartz *et al.*, 2014). Mucorales are known to be haploid and present zygotic meiosis when sexually reproducing (Morin-Sardin *et al.*, 2017). The only documented Mucorales to be amenable to genetic manipulation are *Mucor circinelloides*, and *Rhizopus delemar*. Even in these two fungi, the genetics are challenging due to lack of dominant selection markers, low efficiency of

transformation, and rarity of chromosomal integration. Thus, instead of commonly manipulating genes by disruption, the most utilized tool for gene manipulation relies on silencing gene expression by RNA interference (RNAi) (Calo *et al.*, 2014; Trieu *et al.*, 2017; Ibrahim *et al.*, 2010; Liu *et al.*, 2015). Gene silencing has enabled identification of genes with roles in virulence and drug resistance. Gene disruption by homologous recombination has also been successfully implemented mainly in *M. circinelloides*, and provided valuable information on the role of the calcineurin pathway in mucormycosis pathogenesis (Lee *et al.*, 2015, 2013). The latest advancement in development of molecular tools is the CRISPR/Cas9 system to preform gene editing of genomic DNA. The first report on using this technology in Mucorales was for disrupting a toxin-encoding gene in *R. delemar* using a single plasmid with *pyrF* as a marker and the biolistic delivery system for transformation (Baldin *et al.*, 2017). Gene disruption was confirmed by Southern blot analysis, abrogation of the toxin expression and significant reduction of *R. delemar* to damage host cells (Baldin *et al.*, 2017). The CRISPR/Cas9 was more recently used to produce *R. delemar pyrF* mutants with single nucleotide deletion at the fourth nucleotide before the protospacer adjacent motif (PAM) sequence, which is consistent with CRISPR-Cas9 induced gene mutation through non-homologous end joining (NHEJ) (Bruni *et al.*, 2019). The CRISPR-Cas9 system has also been successfully used in a plasmid-free method to disrupt two genes in *M. circinelloides*, the *carB* encoding phytoene dehydrogenase and the *hmgR2* encoding 3-hydroxy-3-methylglutaryl-CoA reductase (Nagy *et al.*, 2017). These limited set of tools have been invaluable in understanding the genetic response during host-pathogen interactions, and revealing the fundamental role of several regulatory genes.

Role of Morphogenesis

Mucorales fungi are capable of alternating between yeast, spores and mycelia, in response to environmental conditions (Orlowski, 1991). In *Mucor* spp., anaerobiosis and the presence of a fermentable hexose induce yeast growth, whereas oxygen and nutrient limitation conditions lead to hyphal growth (Wolff *et al.*, 2002). Molecular manipulations including gene deletion constructs have identified genes controlling morphogenesis, and this information has led to promising candidates for drug development. For example, by using homologous recombination of upstream and downstream sequences flanking an auxotrophic marker such as *pyrG*, the calcineurin pathway was determined to regulate yeast-mycelium transition and virulence in *M. circinelloides* (Lee *et al.*, 2015). Disruption of the *CnbR* gene (or the addition of calcineurin inhibitors) locked the fungus in yeast form making them significantly less virulent in mice. Besides calcineurin, the cyclic AMP (cAMP) and its target protein kinase A (PKA) reportedly play a role in control of morphogenesis. Interestingly, calcineurin negatively regulates PKA, suggesting a relationship between these two regulatory pathways (Lee *et al.*, 2013). Other proteins involved in the regulation of *M. circinelloides* dimorphism, such as heterotrimeric G proteins and the ADP-ribosylation factors (Arfs), were also identified by related gene deletions (Patiño-Medina *et al.*, 2018).

The size of spores is also known to contribute to virulence. In a heterologous wax moth larva mucormycosis model, large multinucleate spores that germinate more rapidly, exhibit higher virulence compared to small mononucleate spores (Li *et al.*, 2011). The larger spores can also germinate inside and overwhelm macrophages, while small spores can be digested more rapidly by the innate immune cells. This phenomenon is not unusual, since another human-pathogenic fungus, *Cryptococcus neoformans*, is also known to similarly produce mononucleate but polyploid giant/titan cells, which are less susceptible to the host immune system (Zaragoza *et al.*, 2010; Okagaki *et al.*, 2010).

Role of Iron uptake

Mucorales possess sophisticated mechanisms to acquire iron from the host, a metal vital for fungal survival (Howard, 1999). In the host, iron is chelated by proteins such as ferritin, lactoferrin and transferrin (Howard, 1999). In patients with hyperglycemia, diabetic ketoacidosis, or other forms of acidosis, elevated blood sugar and low blood pH levels destabilize the ability of host iron chelators, resulting in elevation of the concentration of serum free iron (Artis *et al.*, 1982; Gebremariam *et al.*, 2016; Ibrahim, 2014). Elevated serum free iron increases the possibility of infection with mucormycosis. Mucorales have two different strategies for iron acquisition: a high-affinity iron uptake system and the production of siderophores (Lax *et al.*, 2020; Carroll *et al.*, 2017; Navarro-Mendoza *et al.*, 2018). The high-affinity iron uptake mechanism is composed of a triad of proteins strictly regulated by iron levels: a family of iron reductases (Fre), a ferroxidase (Fet3), and a high affinity iron permease (Ftr1) (Navarro-Mendoza *et al.*, 2018). Low availability of iron triggers the expression of the high-affinity iron uptake mechanism in *R. delemar* (Ibrahim *et al.*, 2010; Liu *et al.*, 2015; Fu *et al.*, 2004), *M. circinelloides* (Navarro-Mendoza *et al.*, 2018), and *L. corymbifera* (Schwartz *et al.*, 2014). Functions of genes associated with iron uptake in Mucorales have been investigated using RNAi gene silencing, especially in the case of *R. delemar* (previously identified as *R. oryzae*) which is less amenable to mutagenesis than *M. circinelloides* (Ibrahim *et al.*, 2010). Reduction of the relative copy number of the *FTR1* gene or the inhibition of its expression by RNAi compromises the ability of *R. delemar* to acquire iron *in vitro* and reduces its virulence in diabetic ketoacidotic mice (Ibrahim *et al.*, 2010). Dialysis patients, who are treated with deferoxamine to alleviate iron-overload toxicity, are uniquely predisposed to a lethal form of mucormycosis (Boelaert *et al.*, 1987, 1989, 1991, 1994). *R. delemar* utilizes iron from ferrioxamine (the iron-rich form of deferoxamine) to boost its growth. Biochemical and genetic analyses (by RNAi-mediated gene silencing) identified two surface proteins/receptors (Fob1 and Fob2) in *R. delemar* that bind ferrioxamine and facilitate iron uptake via a reductase/Ftr1-mediated mechanism (Liu *et al.*, 2015). In *M. circinelloides*, three ferroxidases genes have been characterized, *fet3a*, *fet3b*, and *fet3c* (Navarro-Mendoza *et al.*, 2018). All three genes are overexpressed in the lungs of mice intravenously infected with *M. circinelloides* and are regulated by the

availability of iron in the culture media, and the fungal dimorphic state with *fet3a* specifically expressed in yeast growth, while *fet3b* and *fet3c* being expressed in hyphae during aerobic growth (Navarro-Mendoza *et al.*, 2018). Furthermore, gene deletion studies showed a predominant role for *fet3c* *in vivo* virulence of *M. circinelloides* (Navarro-Mendoza *et al.*, 2018).

In addition to utilizing the bacterial deferoxamine as a xenosiderophore, *Rhizopus* produces rhizoferrin to chelate iron (Carroll *et al.*, 2017; Thieken and Winkelmann, 1992; de Locht *et al.*, 1994). A rhizoferrin synthetase (*rfs*) was identified in *R. delemar* based on homology to the bacterial NRPS-independent siderophore (NIS) protein, SfnAD, and was found to contain a C-terminus conserved ferric iron reductase FhuF-like transporter domain. Furthermore, the *rfs* expression in *R. delemar* was repressed by iron and *E. coli* cells expressing *rfs* were able to synthesize siderophore from citrate and diaminobutane. Finally, site directed mutagenesis of selected conserved residues revealed that H484 is essential for the *rfs* activity (Carroll *et al.*, 2017). However, the role of the *rfs* gene in mucormycosis pathogenesis is yet to be determined.

CotH Proteins and Angioinvasion

To cause angioinvasion, Mucorales actively interact with the endothelium lining blood vessels. CotH family members are kinase-like proteins (Nguyen *et al.*, 2016) that are universally present in Mucorales and absent from any other forms of life (Gebremariam *et al.*, 2014; Chibucos *et al.*, 2016). These are cell-surface proteins that have been reported to act as invasins in invading host tissues via interacting with the endothelium. Copy number of CotH genes correlates with the pathogenic potential of the agents of mucormycosis, with the pathogenic species most isolated from infections (*Rhizopus*, *Mucor*, and *Lichtheimia*) having five to seven copies of the gene (Chibucos *et al.*, 2016). In *R. delemar* which contains six CotH encoding genes, CotH3 protein, and to a lesser extent CotH2 protein, bind to glucose-regulated protein 78 kDa (GRP78) receptor on human umbilical vein endothelial cells (Gebremariam *et al.*, 2014; Liu *et al.*, 2010). GRP78 is a heat-shock protein of the HSP70 family, that localizes to the cell surface of mammalian cells during stress conditions (Ibrahim *et al.*, 2019; Lee, 2007). Moreover, diabetic host factors such as hyperglycemia, elevated available serum iron, and the presence of ketone bodies (e.g., β -hydroxy butyrate), are known to enhance the expression of GRP78 and CotH3 *in vitro* and in the target organs of diabetic ketoacidotic mice (sinus, lungs and brains), resulting in augmentation of fungal invasion of endothelial cells and increased disease severity in mice (Gebremariam *et al.*, 2016; Liu *et al.*, 2010). This increased expression level was further demonstrated by immunohistochemistry of the ethmoidal sinus tissue of a patient with rhinocerebral mucormycosis, revealing GRP78 intense expression on infiltrated endothelial cells and macrophages in necrotic tissues (Shumilov *et al.*, 2018). Consistent with these results, blocking the function of CotH3 proteins either biochemically by using anti-CotH antibodies or genetically by attenuating CotH3 expression, reduces the ability of *R. delemar* to invade and injure endothelial cells *in vitro* and reduces disease severity in mice (Gebremariam *et al.*, 2014). Therefore, the unique enhancement of interaction between CotH3 and GRP78 under hyperglycemic/ketoacidotic conditions explain the specific susceptibility of diabetic ketoacidotic patients to mucormycosis. Of critical importance is the isolation of anti-CotH3 monoclonal antibodies that are partially protective when given alone against murine mucormycosis induced by several Mucorales. A single dose of the most protective monoclonal antibody shows complete protection of diabetic ketoacidotic mice from *R. delemar* lethal infection when used in combination with clinically used antifungal agents (Gebremariam *et al.*, 2019). Fig. 2, summarizes the pathogenesis and host immune response during mucormycosis.

The fact that rhinoorbital/cerebral and pulmonary mucormycosis are acquired by inhalation of spores from the environment, yet they specifically afflict diabetic ketoacidosis and immunocompromised patients, respectively, is intriguing. In a recent study, the unique susceptibility of diabetic ketoacidotic subjects to rhinoorbital/cerebral form of the disease was likely found to be due to specific interactions between the nasal epithelial cell GRP78 and fungal CotH3, the expression of which increase in the presence of host factors present in diabetic ketoacidosis (Alqarihi *et al.*, 2020). This results in trapping inhaled spores within the nasal cavity, resulting in damage of adjoining tissues. In contrast, interaction of Mucorales with alveolar epithelial cells was initiated by a different fungal cell surface protein of the CotH family, CotH7, with integrin β 1 receptor of the alveolar epithelial cells. Integrin β 1 in turn activates EGFR to induce fungal invasion of alveolar epithelial cells (Alqarihi *et al.*, 2020). These results highlight that, Mucorales ligands recognize host receptors unique to individual cell types (i.e., alveolar, nasal, endothelial cells), and that this fungal ligand-host receptor interaction is enhanced by host factors, eventually leading to infections in the respective host niches.

Diagnosis

Delaying amphotericin B-based therapy beyond 5 days of onset of symptoms doubles 12-week mortality in patients with hematological malignancies (Chamilos *et al.*, 2008). Therefore, early diagnosis of mucormycosis is key for timely implementation of appropriate therapy (Spellberg *et al.*, 2012). The conventional definitive diagnosis of mucormycosis relies on culturing the organism from usually sterile body sites and/or tissue histopathology since currently there is no serology test for diagnosis of mucormycosis (Sugar, 2005; Spellberg *et al.*, 2005a; Cornely *et al.*, 2019). Mucorales can be isolated on media such as Sabouraud-dextrose agar incubated at 25–37°C and fungal elements can be stained with Gomori methenamine-silver, hematoxylin and eosin (H&E), periodic acid-Schiff (PAS) or calcofluor white stain to visualize tissue invasion (Lass-Flörl, 2009). However, these techniques are not sensitive enough, and often lead to a misdiagnosis. For example, cultures can lead to false positives owing to the ubiquitous nature of Mucorales fungi. In contrast, lack of growth sometimes can be a sign of

Fig. 2 Diagram illustrating the interactions of *R. delemar* 99–880 with epithelial and endothelial cells during invasion and hematogenous dissemination. (1) *R. delemar* CotH7 ligand interacts with the alveolar cell receptor, integrin $\alpha 3 \beta 1$ which activates EGFR leading to invasion and damage of the alveolar epithelium. (2) *R. delemar* is resistant to killing by alveolar macrophages. (3) In deferoxamine-treated patients, ferrioxamine binds to fungal Fob1 and Fob2 leading to internalization of host iron via the high affinity reductase/permease system (Ftr1). (4) Elevated glucose (Glu), iron (Fe), β -hydroxy butyrate (BHB) in the blood of diabetic ketoacidotic patients enhance the expressions of GRP78 and CotH3 leading to invasion and damage of the endothelium and augmentation of fungal growth. (5) Using anti-CotH3 antibodies can block the fungal ligand from interacting with host GRP78 leading to less invasion and damage to the endothelial cells. (6) Sodium bicarbonate (NaHCO_3) reverses the effect of acidosis (i.e., elevated BHB and free iron), thereby halting the growth of the fungus and preventing further invasion and hematogenous dissemination.

laboratory mishandling of the specimen (e.g., homogenization can destroy hyphal elements and kill the fungus) resulting in false negatives (Spellberg and Ibrahim, 2015). Definitive diagnosis relying on histopathology can also lead to errors despite the distinctive nature of the board ribbon-like aseptate Mucorales hyphae and often occurs at a late stage of the infection, thereby resulting in little influence on the outcome of therapy (Dadwal and Kontoyiannis, 2018). Computed tomography (CT) is useful for early detection of pulmonary mucormycosis, particularly in patients with cancer. The presence of a reversed halo sign in patients with a hematologic malignancy or neutropenia carries a high predictive value of mucormycosis and along with the absence of airway-invasive features, may help differentiate the condition from invasive pulmonary aspergillosis (Spellberg et al., 2009b; Jung et al., 2015; Legouge et al., 2014). However, radiographic signs may be suggestive of disease, but are rarely diagnostic (Spellberg et al., 2005a).

Recent advances in molecular diagnostics, including the development of polymerase chain reaction (PCR)-based technologies, as well as Matrix Assisted Laser Desorption/Ionization-Time of Flight Mass Spectrometry (MALDI-TOF MS), have the potential to hasten both the diagnosis of mucormycosis and the initiation of appropriate treatment.

Molecular diagnostics

Real-time PCR-based techniques have emerged as a promising new modality to aid in diagnosis of mucormycosis, especially in pulmonary diseases caused by *Lichtheimia*, *Mucor*, *Rhizopus*, and *Rhizomucor* spp. (McCarthy et al., 2017; McCarthy and Walsh,

2016). Amplification of CotH3, a protein specific for Mucorales, has proven to be highly specific and sensitive for diagnosis of mucormycosis (Baldin *et al.*, 2018). CotH3 was shown to be successfully amplified from urine, plasma, and bronchoalveolar lavage retrieved from mice infected with Mucorales fungi but not from mice infected with *Aspergillus fumigatus* (Baldin *et al.*, 2018).

A multiplex real-time PCR (MRT-PCR) platform to detect DNA from the most frequent agents of mucormycosis has also been developed (Nagao *et al.*, 2005; Walsh *et al.*, 2012). Primers and molecular beacon probes have been designed on the basis of the nucleotide sequence of the ITS1 ribosomal DNA region from strains belonging to *R. oryzae*, *R. microsporus* as well as the sequence of the ITS2 region for *Mucor* spp. belonging to *M. circinelloides*, *M. racemosus*, *M. plumbeus* and *M. velutinosus* (Bernal-Martínez *et al.*, 2013).

A semi-nested PCR-based assay amplifying the 18S region of rDNA specific to Mucorales was shown to be more reliable in detecting infection in tissue and serum samples from patients with rhinoorbital/cerebral mucormycosis than using ITS2 PCR (Zaman *et al.*, 2017). Other quantitative PCR methods have evaluated a combination of hydrolysis probes targeting *Mucor*/*Rhizopus*, *Lichtheimia*, and *Rhizomucor* for circulating Mucorales detection in patients with confirmed mucormycosis (Millon *et al.*, 2013). DNA from Mucorales was detected in 9 of 10 serum samples from patients with proven disease, suggesting quantitative PCR could be a useful screening tool in high-risk patients (Caillot *et al.*, 2016).

Other promising strategies such as matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) have been used to identify Mucorales (Yaman *et al.*, 2012). However, MALDI-TOF MS has not been validated for diagnosis of mucormycosis in clinical samples. Besides, the need for prior culture of fungi before identification, and lack of robust libraries for rare Mucorales limits this diagnostic tool.

Treatment of Mucormycosis

Major steps in treatment of mucormycosis involve surgical debridement of involved tissues, antifungal therapy and implementation of approaches that reverse risk factors like neutropenia, hyperglycemia, or ketoacidosis (Chitasombat and Kontoyiannis, 2016; Kontoyiannis and Lewis, 2011).

Surgery

Surgical debridement has to be conducted as early as possible and should be extensive, involving all necrotic areas often leading to disfigurement, especially in the case of rhinoorbital/cerebral infection (Vironneau *et al.*, 2014). Many uncontrolled studies have documented that local control of the disease in patients with rhinoorbital/cerebral mucormycosis, with wide and repeated surgical debridement is associated with improved outcomes (Gil-Lamagnere *et al.*, 2005; Chamilos *et al.*, 2010; Potenza *et al.*, 2011). Local control of infection was obtained in 90% of the patients after radical surgery versus 41.6% in patients who had limited surgery (Vironneau *et al.*, 2014).

Currently Approved Antifungal Drugs

An early intervention with antifungal drugs is key for improved outcome of infection with mucormycosis. Lipid formulations of amphotericin B (e.g., liposomal amphotericin B [L-AMB]) has been the treatment of choice, since it can be administered in higher doses without the accompanying nephrotoxicity associated with conventional amphotericin B formulations (Cornely *et al.*, 2019; Vehreschild *et al.*, 2013; Fera *et al.*, 2009). Alternative treatment regimen encompass using broad-spectrum oral triazoles such as posaconazole and isavuconazole as a “step-down” treatment after the primary administration of L-AMB (Kontoyiannis and Lewis, 2011; Allen *et al.*, 2015; Marty *et al.*, 2016). Because mucormycosis is a rare disease, there are no randomized trials assessing the efficacy of the antifungal drugs. However, a multicenter open-label single-arm study (VITAL study) including 37 patients with mucormycosis showed that treatment with isavuconazole alone had outcomes comparable to that of L-AMB, or L-AMB followed by posaconazole (Marty *et al.*, 2016). These data are mirrored by comparative efficacy of isavuconazole to L-AMB in treating murine mucormycosis (Luo *et al.*, 2014; Gebremariam *et al.*, 2017b). While any combination studies between isavuconazole and lipid formulation amphotericin are lacking, combination treatment of therapeutic doses of L-AMB and posaconazole have no benefit over L-AMB treatment in experimental models of mucormycosis (Ibrahim *et al.*, 2009).

Mucorales species demonstrate *in vitro* resistance to echinocandins despite harboring the echinocandin-target enzyme FKS required for 1,3- β -glucan synthesis (Ibrahim *et al.*, 2005a). Therefore, echinocandins are not used as stand-alone therapy for mucormycosis (Bassetti and Bouza, 2017). However, animal model investigations have shown evidence of synergism between echinocandins and lipid formulation amphotericin B (Spellberg *et al.*, 2005b; Ibrahim *et al.*, 2008a). Furthermore, a retrospective study of 41 diabetic patients with rhinoorbital/cerebral mucormycosis treated with a combination of lipid formulation amphotericin B and caspofungin acetate had a higher survival outcome than those treated with the polyene alone (Reed *et al.*, 2008). It is assumed that the ability of echinocandins to degrade a small amount of β -glucan on the cell wall of Mucorales, unmasks immune epitopes, thereby facilitating immune recognition and phagocytosis of invading hyphae (Lamaris *et al.*, 2008).

A recent retrospective cohort study of combination L-AmB with posaconazole, L-AmB with echinocandins, and posaconazole with echinocandins showed no differences in 6-weeks mortality between monotherapy and combination treatment in mucormycosis patients with hematologic malignancies and hematopoietic cell transplant recipients (Kyvernitakis *et al.*, 2016). These data

are consistent with the murine data, which showed very marginal benefit for L-AMB + micafungin therapy over L-AMB alone (Ibrahim *et al.*, 2008a). Taken all together, the human retrospective and the murine experimental data suggest that a combination of lipid formulation amphotericin and echinocandins are likely to benefit mucormycosis patients who suffer from diabetic ketoacidosis rather than those with hematologic malignancies and hematopoietic cell transplant recipients. Therefore, any future clinical trials to evaluate the efficacy of polyenes + echinocandins should be conducted in diabetic ketoacidotic patients. While the approach to antifungal therapy remains somewhat controversial (Kyvernitakis *et al.*, 2016), other aspects of care, including reversal of immunosuppression, correction of metabolic deficits, and when appropriate, surgical debridement, remain hallmarks of effective treatment (Cornely *et al.*, 2019; Kyvernitakis *et al.*, 2016).

Investigational Antifungal Drugs

Recently, there has been development of newer investigational drugs in the pipeline, which demonstrate promising activity *in vitro* and in experimental models of mucormycosis. For example, the 1-tetrazole fungal-specific 14 α -lanosterol demethylase (CYP51) inhibitor, VT-1161 showed equal efficacy to high dose L-AMB in delayed therapy model of immunosuppressed mice infected with *R. arrhizus* var. *arrhizus* (Gebremariam *et al.*, 2015). The same drug and posaconazole comparably improved survival and lowered tissue fungal burden of immunosuppressed mice infected with *R. arrhizus* var. *arrhizus* when used in prophylactic therapy. Further, in the continuous therapy, VT-1161 outperformed posaconazole in prolonging mouse survival time (Gebremariam *et al.*, 2017a). Another antifungal drug with promising outcomes against *Rhizopus* species is manogepix (formerly APX001A and E1210). Manogepix has a novel mechanism of action targeting Gwt1 protein which is involved in the conserved glycosylphosphatidylinositol (GPI) post-translational modification pathway (Umemura *et al.*, 2003). In two invasive pulmonary mice models infected with either *R. arrhizus* var. *arrhizus* or *R. arrhizus* var. *delemar*, treatment with fosmanogepix (the prodrug of manogepix) significantly increased and prolonged median survival time of mice post infection, when compared to placebo. In addition, administration of fosmanogepix resulted in a 1–2 log reduction in both lung and kidney fungal burdens. In fact, tissue clearance and survival were comparable to clinically relevant doses of isavuconazole, which is FDA- and EMA-approved for the treatment of patients with mucormycosis (Gebremariam *et al.*, 2020).

Adjunctive Therapies

As mentioned above, reversal of immunosuppression and inherent risk factors is paramount for control of mucormycosis, along with surgery and appropriate early antifungal agents. Given the relatively poor prognosis associated with the disease, adjunct treatment options have emerged, including iron chelation, hyperbaric oxygen, and immunomodulation (Ibrahim *et al.*, 2008b; Yohai *et al.*, 1994; Walsh *et al.*, 2014).

In patients with diabetic ketoacidosis, reversal of acidemia by administration of sodium bicarbonate partially blocked the ability of *R. delemar* to invade endothelial cells, restored the ability of the host to chelate iron, and improved neutrophil function (Fig. 2) (Gebremariam *et al.*, 2016). Additionally, treatment of ketoacidotic mice with sodium bicarbonate specifically protected them from invasive pulmonary infection, suggesting that patients with diabetic ketoacidosis suspected of having mucormycosis might benefit from reversing acidemia by insulin and sodium bicarbonate administration (Gebremariam *et al.*, 2016).

The use of iron chelators that cannot be utilized by Mucorales as siderophores, such as deferasirox and deferiprone, have been shown to reduce available iron, inhibit the fungal growth, and protect diabetic ketoacidosis mice from mucormycosis (Ibrahim *et al.*, 2006; Ibrahim *et al.*, 2007). While case reports suggest a benefit in using iron chelation therapy as an adjunctive treatment in diabetic patients (Spellberg *et al.*, 2009a), a small (20 patient) multi-centered, placebo-controlled, double-blinded study (DEFEAT Mucor) conducted mainly in patients with hematologic malignancies showed an adverse effect of adding deferasirox to L-AMB treatment (Spellberg *et al.*, 2012). Although population imbalances in this small Phase II study make generalizable conclusions difficult, the data do not support a role for initial adjunctive deferasirox therapy for mucormycosis in hematologic malignancies patients.

Another therapy that is likely to be beneficial when combined with surgery and antifungal therapy, particularly in diabetic patients, is the use of hyperbaric oxygen (HBO). HBO administration increases oxygen pressure and improves neutrophil function. In a review of 28 cases, adjunctive HBO was beneficial in diabetic patients (94% survival), but not in patients with hematologic malignancies or bone marrow transplants (33% survival; $p < 0.02$) (Price and Stevens, 1980; John *et al.*, 2005; Barratt *et al.*, 2001; Kajs-Wyllie, 1995; Ferguson *et al.*, 1988). Prolonged courses of HBO were associated with a higher survival (John *et al.*, 2005).

Strategies that augment the immune system, such as administration of granulocyte (macrophage) colony stimulating factor or interferon- γ have been proposed as adjunct therapy, based on limited *in vitro* data and case-reports (Gil-Lamaignere *et al.*, 2005; Abzug and Walsh, 2004). A recent report showed that combination of Interferon- γ with nivolumab (a monoclonal antibody that decreases programmed death-1 (PD-1) expression on T-cells), has proven to be successful in an immunosuppressed patient with intractable mucormycosis (Grimaldi *et al.*, 2017).

Conclusions and Future Perspectives

Mucormycosis caused by Mucorales fungi is a life-threatening infection afflicting mainly immunocompromised patients and less commonly immunocompetent individuals. Global surveillance for mucormycosis is lacking because it is not a reportable disease.

Hence, a public-health based surveillance is essential to improve understanding of their epidemiology and to prioritize research efforts. Such information will not only stratify susceptible patients based on their underlying risk factors, but also open avenues to designing better therapeutic options.

Management of mucormycosis hinges upon correction of underlying conditions such as minimization of the duration of neutropenia (e.g., G-CSF and GM-CSF), prompt correction of hyperglycemia and acidosis, prevention and treatment of thrombocytopenia, and avoiding or tapering down treatment with immunosuppressants. Surgical removal of infected foci whenever possible is also a cornerstone in the successful treatment of mucormycosis. Lipid formulation of amphotericin B remains the first line therapy against mucormycosis, with isavuconazole and posaconazole being alternative options to patients who are refractory or intolerant to polyenes. As a representative of a new class of antifungals targeting GPI-anchored proteins, the investigational drug fosmanogepix, carries heightened promise for adding to the current antifungal agents used to treat mucormycosis. However, management of mucormycosis remains a challenge especially with the lack of rapid, reliable and affordable diagnostic tools.

A thorough understanding of Mucorales virulence factors and their role in interaction with host receptors and the innate immune system is of paramount importance. Identification of these targets carries the promise of designing and implementing novel strategies against the disease. Recent molecular pathogenesis investigations have identified several strategies including the CotH3 invasion protein, the calcineurin-dependent hyphal formation pathway, the implementation of sodium bicarbonate to reverse acidosis in patients suspected of mucormycosis, and the repurposing of FDA-approved anti EGFR signaling inhibitors. Although mucormycosis cases have been steadily increasing in numbers over the last three decades, the disease remains to be rare in many parts of the world and this will complicate future clinical trials to evaluate new modalities of treatment. In the absence of comparative clinical trials, pragmatic studies (such as single-arm open label trials [e.g., VITAL study (Marty *et al.*, 2016)]) aided by comprehensive registries should help overcome publication bias and report both positive and negative outcomes of infections treated with these schemes.

Glossary

Arthroconidia Fungal asexual reproductive cell originated from segmentation of hyphae.

Conidia Fungal asexual cell.

Endemic mycosis Mycosis that occur in a specific geographic region.

Etiological agent Causative agent of an infectious disease.

Hematogenous dissemination Dissemination of a pathogen through blood vessels.

Hyphae Fungal elongated multicellular filaments.

Mycelium An aggregate of hyphae cells.

Saprophytic organisms Organisms that inhabit decaying organic matter.

Spores Fungal sexual cell.

Teleomorph Fungal sexual reproductive stage.

Thermal-dimorphic fungi Fungal species that alternate morphology into yeasts and hyphae cells during their lifecycle.

Yeasts Fungal unicellular organisms that reproduce by fission or budding.

Introduction

Dimorphic fungi are organisms that have the ability to switch between two morphologies during their lifecycle: yeast and hyphae (Gauthier, 2015; Klein and Tebbets, 2007). Dimorphism can be induced by several stimuli, such as oxygen concentration, nutrient sources and enzymatic activity (Gauthier, 2015). Thermal-dimorphic fungi are a group of ascomycetes in which morphologic changes are induced by temperature. This group includes species of the genera *Blastomyces*, *Coccidioides*, *Histoplasma*, *Paracoccidioides*, *Sporothrix*, *Talaromyces* and the brand new *Emergomyces* (Boyce and Andrianopoulos, 2015; Gauthier, 2015; Schwartz *et al.*, 2019). These fungi have a very special characteristic: the ability to parasite the mammal host, causing deep mycoses that are usually restricted to specific geographical areas (Fig. 1), also called endemic mycosis (Bonifaz *et al.*, 2011; Rappleye and Goldman, 2006). They are often habitants of soil, in temperatures varying between 22 and 25°C, where they grow was a mold. When fungal propagules such as conidia are inoculated in the mammalian host (~37°C), they undergo a very complex process and convert into pathogenic yeasts or spherules (Klein and Tebbets, 2007; Bonifaz *et al.*, 2011; Rappleye and Goldman, 2006). Morphological transition is a key factor for pathogenicity and its failure almost always attenuates fungal virulence (Garber, 2001; Klein and Tebbets, 2007). Thermal-dimorphic fungi are important human pathogens with significant impact on public health, causing substantial morbidity and mortality (Knox and Hage, 2010; López-Martínez and Méndez-Tovar, 2012; Marques, 2012; Nguyen *et al.*, 2013; Mahajan, 2014; Garber, 2001; Sil and Andrianopoulos, 2015).

Coccidioidomycosis, histoplasmosis, paracoccidioidomycosis, blastomycosis, sporotrichosis, penicilliosis and the recently described emergomycosis are the most common endemic systemic mycoses. Each of these diseases differ in epidemiology, symptoms and prognosis (Bonifaz *et al.*, 2011). Infections are often started in the lungs after inhalation of dormant conidia or spores produced during the differentiation of hyphal cells for asexual or sexual reproduction, from where hematogenous and lymphatic dissemination can occur to the skin and other organs, especially in immunocompromised hosts (Bonifaz *et al.*, 2011; Klein and Tebbets, 2007). Once inside the host, fungal propagules are recognized by host innate immune cells, such as macrophages and neutrophils, inducing a variety of cellular responses (Boyce and Andrianopoulos, 2015; Romani, 2011; Bonifaz *et al.*, 2011). Some of these fungi developed sophisticated strategies to modulate the host immune responses in their favor (Boyce and Andrianopoulos, 2015; Rappleye and Goldman, 2006).

Thermal-dimorphic fungi typically invade immunocompetent hosts. In the United States, it is estimated that *Histoplasma capsulatum* and *Coccidioides spp.* infect 500,000 and 150,000 persons annually, respectively (Gauthier, 2015), and together with *B. dermatitidis*, they are considered to be the most common cause of lung fungal infections in immunocompetent individuals (Sil and Andrianopoulos, 2015). Paracoccidioidomycosis and Emergomycosis are the most prevalent systemic mycosis in Brazil (Coutinho *et al.*, 2015) and South Africa (Schwartz *et al.*, 2019), respectively. However, after the Acquired Immunodeficiency Syndrome (AIDS) pandemic and the developments in modern medicine, such as the immunosuppressive therapy for malignant and autoimmune diseases, and organ transplantation, the incidence of the endemic mycosis has been progressively increasing (Garber, 2001; Mahajan, 2014; Friedman and Schwartz, 2019). In solid organ transplant recipients, thermally dimorphic fungi account for 5% of fungal infections (Gauthier, 2015; Pappas *et al.*, 2010). Life-threatening mycoses occur in both immunocompetent and immunocompromised hosts (Garber, 2001), encouraging the development of new therapies and strategies to overcome these important fungal diseases. In the following sections we will discuss the major characteristics of the main thermal-dimorphic fungal pathogens.

Fig. 1 Approximate geographic distribution of the major thermal-dimorphic fungal pathogens. *Coccidioides immitis* (●), *C. posadasii* (●), *Histoplasma capsulatum* var. *capsulatum* (●), *H. capsulatum* var. *duboisii* (●), *Sporothrix albicans* (●), *S. brasiliensis* (●), *S. mexicana* (●), *S. globosa* (●), *S. schenckii* (●), *Paracoccidioides brasiliensis* (●), *P. americana* (●), *P. restrepiensis* (●), *P. venezuelensis* (●), *P. lutzi* (●), *Blastomyces dermatitidis* (●), *B. percursor* (●), *B. helicus* (●), *Talaromyces marneffeii* (●), *Emergomyces pasteurianus* (●), *Es. africanus* (●), *Es. canadensis* (●), *Es. orientalis* (●) and *Es. europaeus* (●). Map by maptive©.

Coccidioides immitis and *C. posadasii*

The first report of *Coccidioides* infection was made in 1892 by Alejandro Posadas and Robert Wernicke, who identified coccidia-like organisms in unusual skin lesion of a soldier in Argentina (Posadas, 1892; Wernicke, 1892; Sil and Andrianopoulos, 2015; Fisher et al., 2002). In 1894, Emmet Rixford described the first case in North America (Rixford, 1894; Sil and Andrianopoulos, 2015) and in 1896 the “protozoal” organism was formally named *Coccidioides immitis* (Rixford and Gilchrist, 1896). Only in 1900, William Ophuls and H.C. Moffit accurately classified it as an ascomycete fungus belonging to the order Onygenales (Sil and Andrianopoulos, 2015; Ophuls and Moffitt, 1900). Over a century later, using molecular tools and phylogenetic analysis, it was proposed that *C. immitis* actually consisted of two non-interbreeding taxa, resulting in its division into two different species: *C. immitis* and *C. posadasii* (Fisher et al., 2002).

Coccidioides spp. grow as saprophytic organisms in soil of arid and semiarid regions, with very low precipitation and extreme temperature variations (0–45°C) (Bonifaz et al., 2011; Fisher et al., 2007; Kollath et al., 2019). In the environment, *Coccidioides* species have a filamentous morphology. During fungal lifecycle, some hyphae cells differentiate and originate arthroconidia (Garber, 2001; Nguyen et al., 2013). Conidia can spread and grow in the environment originating new hyphae. However, *C. immitis* and *C. posadasii* also have the ability to parasite mammal hosts such as horses, dogs and humans (Bonifaz et al., 2011; Sil and Andrianopoulos, 2015; Nguyen et al., 2013). Sexual structures have never been observed in either species, although molecular data suggest the existence of a teleomorphic phase (Nguyen et al., 2013; Mandel et al., 2007).

C. immitis and *C. posadasii* are the etiological agents of Coccidioidomycosis, commonly known as the Valley Fever. The infection usually starts via the respiratory route (98%), when environmental arthroconidia are inhaled, although rare cases of skin inoculation have been reported (Kollath *et al.*, 2019; Bonifaz *et al.*, 2011). Inside the host, these structures undergo a transition into spherules, a unique structure to the genus *Coccidioides*. Spherules are a large specialized cellular structure with a double membrane that contains up to 300 endospores, which can be released and spread to other tissues after the spherule rupture (Nguyen *et al.*, 2013). Coccidioidomycosis, can have a variety of outcomes. Infection can be asymptomatic (60% of cases) or lead to fungal pneumonia 1–3 weeks after exposure to arthroconidia in endemic areas (Valdivia *et al.*, 2006; Stockamp and Thompson, 2016; Smith and Beard, 1946). It is estimated that spontaneously cure occurs in approximately 95% of cases. Depending on host immune status and inoculum size, infection can develop diffuse pneumonia, a more severe form of the disease, with high mortality rates associated due to acute respiratory distress syndrome (ARDS). Dissemination through hematogenic and lymphatic routes often occurs into bones, skin, lymph nodes and joints (Stockamp and Thompson, 2016; Nguyen *et al.*, 2013). However, the most life-threatening outcome is central nervous system dissemination, causing coccidioidal meningitis, which is generally fatal when left untreated (Stockamp and Thompson, 2016).

Coccidioides spp. distribution has been mostly obtained by epidemiological data from clinical cases and population skin testing for spherulin or coccidioidin (coccidial antigen preparations from spherules and mycelium, respectively), besides soil isolation (Brown *et al.*, 2013b; Stockamp and Thompson, 2016; Edwards and Palmer, 1957). *C. immitis* and *C. posadasii* species have distinct geographic distribution (Fig. 1). *C. immitis* is endemic in central and southern California (especially in the San Joaquin Valley) and Northern Mexico (Bonifaz *et al.*, 2011; Brown *et al.*, 2013b; DiCaudo, 2006). *C. posadasii* has a broader distribution, comprising Arizona, Texas, New Mexico, Nevada and Utah, besides some areas in Guatemala, Honduras, Venezuela, Brazil, Argentina and Paraguay (Sil and Andrianopoulos, 2015; Bonifaz *et al.*, 2011; Brown *et al.*, 2013b; Kollath *et al.*, 2019). Several cases outside endemic areas were reported, the majority of them between travellers or people who temporarily relocated to endemic areas. In the United States, from 2011 to 2017, 95,371 cases of coccidioidomycosis were reported to CDC, where most cases were in Arizona (64.4%) and California (32.5%) (Benedict *et al.*, 2019), and from 1990 to 2008, mortality rate was around 0.59 per million person-years (Huang *et al.*, 2012).

Coccidioides spp. infections have been increasing in recent years and became an important public health problem in endemic areas. Disease affects all age groups, but the highest incidence rates are between adults above 40 years old (Bonifaz *et al.*, 2011), usually male workers, such as construction and farm workers and people who are frequently exposed to aerosolized arthroconidia through soil manipulation. In 2012, it was described an outbreak among armadillo hunters in Brazil northeastern caused by *C. posadasii* (Brilhante *et al.*, 2012). Epidemics were also reported after windstorms and earthquakes in the USA (Stockamp and Thompson, 2016; Brown *et al.*, 2013b; Schneider *et al.*, 1997; Flynn *et al.*, 1979). African or Filipino descendants are more susceptible to extrapulmonary dissemination (Louie, 1999), suggesting that a host genetic component influences disease outcome. Pregnant women in the third trimester or immediately post-partum are specially vulnerable to severe or disseminated disease. Patients with immunocompromising conditions such as diabetics, AIDS and transplant recipients are also part of the risk-group (Galgiani *et al.*, 2005; Stockamp and Thompson, 2016).

Histoplasma capsulatum

Histoplasma capsulatum was first described by Samuel Darling in 1906 as a protozoan parasite that appeared to have capsules and infect macrophages (Darling, 1906; Sil and Andrianopoulos, 2015; Woods, 2002). In 1948, Chester Emmons isolated it for the first time from soil (Emmons, 1949; Sil and Andrianopoulos, 2015). Nowadays it is clear that *H. capsulatum* have no capsule and is actually an ascomycete fungus that belongs to the order Onygenales (Bonifaz *et al.*, 2011). Two varieties inside the species, *H. capsulatum* var. *capsulatum* and *H. capsulatum* var. *duboisii*, are etiological agents for histoplasmosis in humans, leading to different disease outcomes. Pulmonary and systemic histoplasmosis (classical disease) are associated with *H. capsulatum* var. *capsulatum*, which is found in Americas, Southeast Asia and Africa (Fig. 1). *H. capsulatum* var. *duboisii* is found in Western and Central Africa (Fig. 1) and causes skin and bone lesions (Retallack and Woods, 1999; Cockshott and Lucas, 1964). Phylogenetic analyses point out to seven distinct phylogenetic species inside *Histoplasma* isolates from six continents (Sil and Andrianopoulos, 2015; Kasuga *et al.*, 2003). Sexual reproduction happens during teleomorphic phase, when they are designated *Ajellomyces capsulatus* (Bonifaz *et al.*, 2011; Muniz *et al.*, 2014).

In the environment, *H. capsulatum* (Fig. 2) is a saprobic mold that inhabits rich soil or decaying plant materials associated with large amount of droppings of bat or birds, such as chicken, turkeys or geese (Sil and Andrianopoulos, 2015; Woods, 2002; Bonifaz *et al.*, 2011). High humidity and temperatures between 20 and 30°C are favourable growth conditions (Bonifaz *et al.*, 2011). In São Paulo City (Brazil), isolation of *Histoplasma capsulatum* was reported in up to 34.8% of captured bats (Dias *et al.*, 2011; da Paz *et al.*, 2018; Dos Santos *et al.*, 2018), demonstrating that, due to urban expansion, wild species can reallocate to the city and carry the fungus. This can lead to a relevant impact in public health in big urban areas such as Great São Paulo area, with over 20,000,000 people. There were outbreaks involving cave visitors and people whose house ceilings were contaminated by bats or bird feces (Cury *et al.*, 2001; Vicentini-Moreira *et al.*, 2008; Jülg *et al.*, 2008).

During asexual reproduction, macro and microconidia are produced, which basically differs in size (Sil and Andrianopoulos, 2015; Pine, 1960). When fungal propagules, such as conidia and/or hyphal fragments, are inhaled by the host, they are internalized by phagocytic cells (Bullock, 1993; Sil and Andrianopoulos, 2015), and undergo a transition from mold to budding yeast cells, that is

Fig. 2 Micrograph of yeast (A) and hyphae (B) phases of *Histoplasma capsulatum* (40 ×). Macroscopic colonies of *Histoplasma capsulatum* in Sabouraud Agar. Courtesy of Dr. Maria Adelaide Galvão Dias, Centro de Zoonoses do Município de São Paulo, Brazil.

essential for virulence. Yeast cells can evade phagocytic killing, multiply inside alveolar macrophages and use the host cell to spread to other organs such as spleen, liver, lymph nodes and bone marrow through hematogenous dissemination (Rappleye and Goldman, 2006; Woods, 2016). Infection through skin is rare, and usually results from injury during activities such as guano production and cleaning of chicken coops (Bonifaz *et al.*, 2011).

There is a large variety of clinical forms that are influenced by extent of exposure and host immunological status. Skin testing with histoplasmin shows that in more than 99% of cases, primary infections in immunocompetent individuals are mild or asymptomatic (Kauffman, 2007; Bradsher, 1996). Acute disease can occur after high inoculum exposure, especially during activities associated with soil disruption, such as farming and construction, often affecting miners, cave explorers, beekeepers and archaeologists (Bonifaz *et al.*, 2011). Deficiency in cell-mediated immunity increases the risk of disseminated and fatal histoplasmosis (Woods, 2002). Infants, AIDS patients, transplant recipients and patients with other immunological disorders are at particular risk for disseminated histoplasmosis (Sil and Andrianopoulos, 2015; Kauffman, 2007). Chronic cavitary histoplasmosis usually happens concomitantly with pulmonary disorder (Kauffman, 2007; Colombo *et al.*, 2011). Chronic progressive disseminated histoplasmosis is more frequent in elderly even when immunosuppression is not confirmed (Kauffman, 2007; Colombo *et al.*, 2011). In disseminated disease, it is common involvement of the reticuloendothelial system, skin, gastrointestinal tract, gut and adrenal gland (Kauffman, 2007; Colombo *et al.*, 2011). Occasionally, the meninges are affected (Bonifaz *et al.*, 2011). Skin involvement is more frequent in HIV-positive patients. The clinical forms of classical Histoplasmosis listed above are caused by *Histoplasma capsulatum* var. *capsulatum*. *Histoplasma capsulatum* var. *duboisii* causes the African histoplasmosis, which primarily affects skin, lymph nodes and bones, and is limited to equatorial Africa (Bonifaz *et al.*, 2011). In addition to these two varieties, *Histoplasma capsulatum* var. *farcinosum* is a pathogen of horses (Kasuga *et al.*, 2003).

Histoplasmosis is the most common fungal respiratory infection in the world (Bonifaz *et al.*, 2011). Despite its worldwide distribution, *H. capsulatum* var. *capsulatum* is very prevalent in tropical climate zones such as Central and South America, in the eastern USA and also in southern Mexico (Bonifaz *et al.*, 2011). It is highly endemic in the Ohio and Mississippi River Valleys, with over 90% infected individuals. It is estimated that histoplasmosis causes approximately 25,000 life-threatening infections per year in the Midwestern United States (Woods, 2002; Sil and Andrianopoulos, 2015; Brown *et al.*, 2012). Mortality rates due to disseminated disease are high. In a retrospective study, mortality rate was 31% in immunocompromised patients and 17% in immunocompetent patients (Colombo *et al.*, 2011). All age groups can be affected, and although the rates of positive results on skin testing for sensitivity to antigens of *H. capsulatum* are similar in males and females, histoplasmosis has higher incidence in men around 30–40 years old (Bonifaz *et al.*, 2011).

Sporothrix schenckii Species Complex

Sporothrix spp. infection was first described in 1898 by Benjamin Schenck, who identified the fungus in subcutaneous abscesses (Téllez *et al.*, 2014; Sil and Andrianopoulos, 2015; Schenck, 1898). After many years, based in molecular and phenotypic data, it was demonstrated that *S. schenckii* was not a single species, but a complex comprising at least six cryptic species of clinical and epidemiological interest, with significant differences in geographical distribution, biochemical properties, virulence degree, disease patterns and therapy response (Mahajan, 2014; López-Romero *et al.*, 2011). *Sporothrix schenckii* species complex include *S. albicans* and *S. brasiliensis* (in Brazil), *S. mexicana* (in Mexico), *S. globosa* (in United Kingdom, Spain, Italy, China, Japan, USA, and India), and *S. schenckii* sensu stricto (Mahajan, 2014; Marimon *et al.*, 2006; Marimon *et al.*, 2007). *S. schenckii* sensu stricto, *S. brasiliensis*, and *S. globosa* are mainly associated with human infections (Mahajan, 2014; Marimon *et al.*, 2007). There is evidence that *Ophiostoma schenckii* may represent teleomorphic phase. Besides humans, Sporotrichosis can parasite other mammals such as cats, dogs, rats, armadillos and horses (Téllez *et al.*, 2014). These species belong to the order Ophistomatales.

S. schenckii species complex (Fig. 3) are ascomycetes with worldwide distribution (Fig. 1) and associated with warm and humid climate (Téllez *et al.*, 2014). The fungus is found in soil, plant detritus, decaying wood, hay and sphagnum moss, where fungus usually grows as a saprophytic mycelium (Sil and Andrianopoulos, 2015; Mahajan, 2014; Téllez *et al.*, 2014).

Fig. 3 Micrograph of yeast (A) and hyphal (B) morphology of *Sporothrix* spp. (120 ×). Macroscopic colonies (C) of mycelium (left) and yeasts (right) in Potato Agar.

Mycelium is constituted by septate and thin hyphae, and during asexual reproduction, two categories of conidia are produced: the sympodial conidia and a thick-walled, dark brown individual conidia that show different shapes among *Sporothrix* species (Sil and Andrianopoulos, 2015; López-Romero *et al.*, 2011; Marimon *et al.*, 2007). Yeast cells can also be seen in soil, differently from the other dimorphic fungi discussed herein, indicating that temperature is not a requisite for the morphology transition in these species (Sil and Andrianopoulos, 2015; Brown *et al.*, 2012; López-Romero *et al.*, 2011). Yeast cells, which generally emerge from hyphal cells, divide by budding, and multibudded cells are frequently seen due to slow separation from the mother cell (López-Romero *et al.*, 2011). Both conidia and yeasts can produce melanin, what is variable among different strains of the fungus and is associated to higher virulence (López-Romero *et al.*, 2011). In murine models, *S. brasiliensis* was the most virulent species, while *S. schenckii* and *S. globosa* presented intermediate virulence, and *S. mexicana* and *S. albicans* showed low virulence (Arrillaga-Moncrieff *et al.*, 2009).

Unlike the other dimorphic fungi reviewed herein, infection rarely occurs by inhalation of fungal propagules. Instead, primary route of infection is through superficial injury produced by fungus-contaminated objects of organic material, insect bites (rarely) and cat secretions or scratches (Mahajan, 2014; López-Romero *et al.*, 2011). The average incubation period is 3 weeks (Mahajan, 2014). Inoculum size and location, together with host immune status and strain virulence are important factors in the disease outcome. Professionals handling plant material are at particularly high risk, what explains the reason why men shows much higher frequency of infection (Mahajan, 2014).

Sporotrichosis is characterized by a wide range of clinical illnesses. Primary disease is characterized by cutaneous and subcutaneous infection. In this case, skin and lymphatic vessels surrounding inoculation site are affected, where small papulo-nodules and ulcerative lesions can occur (sporotrichotic chancre) without causing systemic symptoms (Mahajan, 2014). In immunocompromised individuals, particularly AIDS patients, hematogenous spread may lead to extracutaneous infection with visceral and osteoarticular involvement, affecting many parts of the body including the bones, joints, and particularly the central nervous system (López-Romero *et al.*, 2011; Mahajan, 2014; Sil and Andrianopoulos, 2015; Téllez *et al.*, 2014). Another clinical manifestation is pulmonary sporotrichosis, caused by inhalation of conidia (Mahajan, 2014; Téllez *et al.*, 2014).

Although its worldwide distribution, Sporotrichosis incidence is higher in tropical and subtropical climates of America, some Asian countries and Australia, with only a few cases in Europe (López-Romero *et al.*, 2011; Chakrabarti *et al.*, 2014). Sporotrichosis is the most common subcutaneous mycosis in Japan, China, Australia, Central and South America (Mexico, Colombia, and specially Brazil and Peru), and India (along the Sub-Himalayan region) (Mahajan, 2014; Téllez *et al.*, 2014; Sil and Andrianopoulos, 2015; Chakrabarti *et al.*, 2014). Meanwhile, in Europe sporotrichosis is less frequent (Téllez *et al.*, 2014). Epidemic outbreaks were reported in South Africa (with 3000 gold miners), the United States and Western Europe (Téllez *et al.*, 2014; Barros *et al.*, 2011). In Brazil, between 1998 and 2011, sporotrichosis was found in more than 4000 humans and 3.704 cats in Rio de Janeiro, and the most prevalent etiological agent and primary pathogen of feline sporotrichosis was *S. brasiliensis* (Gremião *et al.*, 2015; Pereira *et al.*, 2014; Rodrigues *et al.*, 2013; Silva *et al.*, 2012; Barros *et al.*, 2011).

Paracoccidioides spp.

Paracoccidioidomycosis (PCM) was first described by Adolpho Lutz in 1908 (Lutz, 1945) and for many years its etiological agent was believed to be a single species, *Paracoccidioides brasiliensis*. Almost a century later, phylogenetic studies demonstrated high genetic variability between the isolates, and the taxonomical recognition of five distinct species of the genus *Paracoccidioides* was recently proposed (Turissini *et al.*, 2017). The group is classified in the order Onygenales, where *P. brasiliensis* include isolates from Argentina, Brazil, Peru, Venezuela and Antarctica; *P. americana* (former PS2) includes isolates from Brazil and Venezuela;

Fig. 4 Micrograph of *P. brasiliensis* (A) and *P. lutzii* (B) yeasts (120x). Macroscopic colonies (C) of mycelium (left) and yeasts (right) in BHI Agar.

P. restrepiensis (former PS3) includes isolates from Colombia; *P. venezuelensis* (former PS4) includes isolates from Venezuela; and *P. lutzii* (Pb01-like group) is endemic in the North and Central-West regions of Brazil and Ecuador (Teixeira *et al.*, 2013; Theodoro *et al.*, 2012; Turissini *et al.*, 2017) (Fig. 1). A teleomorphic stage has not been identified yet, although there is evidence for sexual reproduction among some isolates (Sil and Andrianopoulos, 2015; Bocca *et al.*, 2013).

Natural reservoir of *Paracoccidioides* species is not totally determined. However, *Paracoccidioides* spp. have been isolated in soils from Venezuela (de Alborno, 1971), Argentina (Negroni, 1968) and Brazil (Vergara and Martinez, 1998; Naiff *et al.*, 1986). Besides that, isolates in other mammals such as armadillos, dogs, chickens, pigs, cattle, horses, sheep, goats, bats, rabbits and monkeys have been reported (Nucci *et al.*, 2009; Bagagli *et al.*, 1998; Shikanai-Yasuda *et al.*, 2006; da Paz *et al.*, 2018). It is believed that the fungus is a saprophytic mold that grows in humid soil and decaying organic material, with abundance of vegetation and watercourses, specially from coffee, tobacco and sugar cane plantations (Bonifaz *et al.*, 2011; Bocca *et al.*, 2013; Calle *et al.*, 2001; Barrozo *et al.*, 2009). High altitude (1000–1499 meters) and humidity (rainfall from 2000 to 2999 mm) could lead to a great release of conidia and arthroconidia in the air, with a large risk of exposure, explaining a cluster of acute and subacute cases in a southern region of Brazil after 1982/1983 El Niño Southern Oscillation (Barrozo *et al.*, 2009).

Once inside the host, mycelium cells convert to yeast morphology (Fig. 4). Yeast cells divide by budding with slow separation from mother cells, sometimes appearing as multibudded cells (Sil and Andrianopoulos, 2015; Goldani and Sugar, 1995). *Paracoccidioides* yeasts are not predominantly intracellular pathogens; multibudded yeasts are too large to be readily internalized. However, they can infect epithelial and alveolar cells, and this ability to parasitize cells may be important for virulence (Mendes-Giannini *et al.*, 2008; Sil and Andrianopoulos, 2015). *Paracoccidioides* infection starts after inhalation of conidia or arthroconidia or less frequently by skin and mucous membranes injury (Sil and Andrianopoulos, 2015; Martinez, 2015; Bocca *et al.*, 2013). Yeast cells can remain latent for years, a condition known as paracoccidioidomycosis-infection. Primary disease is often characterized by asymptomatic lesions of the lung. Disease manifests as two main clinical forms, which depends on host immune status, and its progression is likely to be associated with some kind of immunodeficiency (Sil and Andrianopoulos, 2015; Martinez, 2015). Children and young adults often develop acute and subacute clinical forms of PCM, with disseminated lesions, and it is likely to appear a few weeks or months after infection. Chronic form manifests months to years after *Paracoccidioides* exposure and is more common among adult men, involving lesions in the oral mucosa, the airways and specially lungs. Extrapulmonary paracoccidioidomycosis affects oropharyngeal mucosa, lymph nodes, skin and various organs (Bonifaz *et al.*, 2011; Shikanai-Yasuda *et al.*, 2006; Bocca *et al.*, 2013). Skin test studies show that men and women are equally infected, but disease is highly prevalent in adult men, probably due to a greater exposure to the fungus during professional activities such as farming (Shikanai-Yasuda *et al.*, 2006; Bocca *et al.*, 2013). In addition to that, unlike the other endemic mycosis discussed here, endogenous estrogens have an important influence during infection, inhibiting the conversion of conidia into yeasts and also modulating the cell immune response so that women have more resistance against disease (Martinez, 2015; Bocca *et al.*, 2013; Restrepo *et al.*, 1984).

Paracoccidioidomycosis is highly endemic in South America (Brazil, Colombia, Venezuela, Paraguay), and some regions of Central America and Mexico (Bonifaz *et al.*, 2011; Sil and Andrianopoulos, 2015). Infection occurs exclusively in Latin American countries (Martinez, 2015), and it is believed that cases observed in the United States of America, Canada, Spain and other European countries, the Middle East, Japan and Africa were actually imported paracoccidioidomycosis (Forjaz *et al.*, 1999; Bocca *et al.*, 2013). Majority of the cases are reported in Brazil, followed by Venezuela, Colombia and Argentina. *P. lutzii* endemic area involves especially the Midwest and North regions of Brazil (Fig. 1). Between 1930 and 2012, over 15,000 cases of Paracoccidioidomycosis have been reported, but this number only partially reflects the prevalence of the disease in Latin America. Epidemiological surveys using paracoccidioidin skin testing demonstrated positive rates ranging from 2% to 82% in Brazil, up to 77% in rural population of Colombia and 10.2%–19.7% in Venezuela and 1.6%–10.7% in Argentina (Magalhães *et al.*, 2014).

Paracoccidioidomycosis is the most common systemic mycosis in Latin America (Sil and Andrianopoulos, 2015; Coutinho *et al.*, 2002) being responsible for 51.2% of systemic fungal infections and occupying the 10th position among infectious diseases of high mortality during 1996–2006 in Brazil (Prado *et al.*, 2009). It is estimated that annual incidence varies from 10 to 30 cases

per million people and mortality rates range from 0.2 to 2.1 deaths per million inhabitants (Nucci *et al.*, 2009; Santo, 2008; Prado *et al.*, 2009; Martinez, 2017), being the highest cause of death among systemic mycoses in Brazil (Bocca *et al.*, 2013). Higher mortality rates of this mycosis were found in the Central and Southeast States, especially São Paulo, Minas Gerais and Rio de Janeiro (Prado *et al.*, 2009). Colombia has lower and variable incidence, with the highest being 2.4 cases per million inhabitants (Torrado *et al.*, 2000; Colombo *et al.*, 2011). Annual incidences of new cases may vary from 1 to 3.7 new cases per 10⁵ inhabitants (Shikanai-Yasuda *et al.*, 2006; Bocca *et al.*, 2013). As so, paracoccidioidomycosis is considered a serious public health problem in endemic areas (Blotta *et al.*, 1999; Shikanai-Yasuda *et al.*, 2006). At the same time, paracoccidioidomycosis is also considered a neglected disease, and its epidemiology is underestimated due to several difficulties, such as the fact that case notification is not obligatory, absence of epidemic outbreaks and poor laboratory diagnostic capacity (Martinez, 2015).

Blastomyces dermatitidis

B. dermatitidis was first described by T.C. Gilchrist as a protozoan parasite that caused skin lesions, in 1894 (Sil and Andrianopoulos, 2015; Gilchrist, 1894). In 1898, Gilchrist isolated and fully described the pathogen as a fungus. These fungi grow in a hyphal form at temperatures below 30°C and as yeasts at 37°C. Teleomorphic phase is called *Ajellomyces dermatitidis*. Environmental niche is likely soil and decaying vegetation, especially in proximity to lakes and rivers, where it grows as mycelium with septate hyphae (Nemecek, 2006; Sil and Andrianopoulos, 2015; Bonifaz *et al.*, 2011; Castillo *et al.*, 2016). Infection occurs after inhalation of conidia or hyphal fragments (rarely through skin injury), and conversion into yeast occurs once inside the host (Castillo *et al.*, 2016; Kauffman, 2007). Yeast cells are characterized by a doubly thick cell wall with the daughter cell often as large as the mother cell before detachment. Inside the host, *B. dermatitidis* grows as extracellular yeasts in microabscesses (Sil and Andrianopoulos, 2015; Kauffman, 2007). Besides humans, *B. dermatitidis* also infects other animals, especially dogs (Castillo *et al.*, 2016; Saccante and Woods, 2010).

Infection is mostly asymptomatic or manifests as a self-limited illness. The disease was considered a localized dermatologic condition for years. However, primary pulmonary blastomycosis is the most important clinical form of disease and can be presented as an acute or chronic infection, with eventual progress to severe lung involvement manifested as acute respiratory distress syndrome (Castillo *et al.*, 2016). High inoculum and defects in cell-mediated immunity can promote a more severe and progressive disease (Bonifaz *et al.*, 2011; Sil and Andrianopoulos, 2015; Castillo *et al.*, 2016). Hematogenous dissemination can involve many organs, specially skin, osteoarticular structures, genitourinary tract and others. Adult men, particularly agricultural workers and farmers, are mostly affected due to higher exposure in the environment (Bonifaz *et al.*, 2011; Sil and Andrianopoulos, 2015; Castillo *et al.*, 2016).

Blastomycosis is one of the three major dimorphic endemic mycoses that occur predominantly in North America (Fig. 1). High incidence is found in Canada (especially in provinces of Quebec, Manitoba, and Ontario) and Eastern USA, specially surrounding the Ohio and Mississippi River valleys (Castillo *et al.*, 2016; Sil and Andrianopoulos, 2015). Middle and East Africa are also endemic sites, and sporadic cases were reported in Argentina (Kruse *et al.*, 2010). Due to its similarities with other common diseases, blastomycosis is often misdiagnosed, particularly as malignancy, what impairs epidemiology data (Bradsher, 2014). In addition to that, skin tests are not available and serologic studies have been considered unreliable due to cross reactivity with other endemic infections. Mortality rates range from 4% to 6% (Castillo *et al.*, 2016), and mortality rates associated with CNS blastomycosis are as high as 18%, and 89% in patients with ARDS (Castillo *et al.*, 2016).

The genus *Blastomyces* has been recently revised to include new species. In 2013, *B. gilchristii* was identified as a genetically divergent clade within *Blastomyces dermatitidis* (Brown *et al.*, 2013a). *B. helices*, former formerly classified in the genus *Emmonia* as *Ea. Helica*, differs from *B. dermatitis* because it predominantly affects immunocompromised patients and appears in the western and mountainous regions of North America (Schwartz, Wiederhold, *et al.*, 2019; Jiang *et al.*, 2018). *B. percursorus* was isolated from patients in South Africa and Israel, and differently from *B. helices*, can also cause disease in immunocompetent hosts (Dukik *et al.*, 2017; Friedman and Schwartz, 2019). Two other new species, *B. parvus* (former *Ea. parva*) and *B. silverae* are pathogens of small mammals (Muñoz *et al.*, 2015).

Talaromyces marneffei

T. marneffei (former *Penicillium marneffei*) was originally described in 1956 from a bamboo rat in Vietnam, but only in 1959 the first human infection was reported after an accidental self-inoculation of a researcher (Sil and Andrianopoulos, 2015; Vanittanakom *et al.*, 2006; Segretain, 1959). In 1973, it was registered the first naturally occurring human case, in an American patient with Hodgkin's disease who was living in the southeast Asia. After that, a few number of cases were reported, until AIDS pandemic arrived in Asia, when the number of infections increased substantially, raising *T. marneffei* as an important human pathogen (Vanittanakom *et al.*, 2006; Chan *et al.*, 2016; Sil and Andrianopoulos, 2015). In Southeast Asia, *T. marneffei* represents an "AIDS-defining pathogen" (Sil and Andrianopoulos, 2015; Vanittanakom *et al.*, 2006; Supparatpinyo *et al.*, 1994). *T. marneffei* is classified into *Eurotiales* order.

Unlike all other species in *Talaromyces* genus, *T. marneffei* is a thermal-dimorphic fungi and the only considered to be pathogenic in humans. *T. marneffei* grows as a mycelium at 25°C, with multinucleate and septate hyphae, producing conidiophores and conidia typical of *Talaromyces* genus (Vanittanakom *et al.*, 2006). Once inside the host (37°C), conidia is phagocytized and undergo transition into yeasts, which reside within these cells and divide by fission (Sil and Andrianopoulos, 2015; Andrianopoulos, 2002). *T. marneffei* biologic niche remains uncertain, and there are only a few reports of isolation from environment. Co-existence with some species of

rodents, such as *Rhizomys sinensis*, *Rhizomys pruinosus*, *Rhizomys sumatrensis* and *Cannomys badius*, has been extensively reported, suggesting that the reservoir may be in fact the rat and raising the possibility that infection occurs as a consequence of zoonotic transmission (Sil and Andrianopoulos, 2015; Vanittanakom and Sirisanthana, 1997; Vanittanakom *et al.*, 2006). However, no correlation of geographic distribution between bamboo rats and human infection has been found. On the other hand, age (16–30 years) and agricultural activities were described as factors associated with increased risk of infection (Sil and Andrianopoulos, 2015; Vanittanakom *et al.*, 2006; Chariyalertsak *et al.*, 1997). It is generally accepted that infection is initiated by inhalation of dormant conidia. However, at this moment, it is not clear if it is a consequence of zoonotic or environmental transmission.

T. marneffei infection (penicilliosis) is endemic in tropical Asia, especially Thailand, north-eastern India, China, Hong Kong, Vietnam, and Taiwan (Fig. 1). In northern Thailand, disease is the third most common opportunistic infection in AIDS patients (Vanittanakom *et al.*, 2006; Supparatpinyo *et al.*, 1994). Another important characteristic of *T. marneffei* infection is that the disease occurs predominantly in immunocompromised individuals, being considered an opportunistic mycosis. Disease starts as a pulmonary infection followed by hematogenous dissemination to the lymphatic system, liver, spleen and bones (Sil and Andrianopoulos, 2015; Kudeken *et al.*, 1996; Vanittanakom *et al.*, 2006). Systemic disease is often fatal when left untreated. Rare cases of disease in immunocompetent individuals have been described, although immunological status of patients was not adequately tested (Sil and Andrianopoulos, 2015).

***Emergomyces* spp.**

A new genus in the order Onygenales has recently been created in order to accommodate five species of thermodimorphic fungal pathogens: *Emergomyces pasteurianus*, *Es. africanus*, *Es. canadensis*, *Es. orientalis* and *Es. europaeus* (Dukik *et al.*, 2017). They are the causative agents of the recently described emergomycosis, a systemic fungal infection that, unlike other endemic mycosis, is primarily affecting immunocompromised individuals, especially HIV patients (Kenyon *et al.*, 2013; Friedman and Schwartz, 2019; Dukik *et al.*, 2017; Schwartz *et al.*, 2019). Emergomycosis has been reported worldwide (Fig. 1): *Emergomyces pasteurianus* in Europe, Asia and Africa; *Es. africanus* in South Africa, *Es. canadensis* in Canada and the USA, *Es. orientalis* in China and *Es. europaeus* in Germany (Schwartz, Maphanga, *et al.*, 2018; Schwartz *et al.*, 2019). *Es. africanus* DNA has been identified in soil (Schwartz *et al.*, 2018) and air (Schwartz *et al.*, 2018) samples in South Africa, and infection is presumably by inhalation of conidia that, once inside the human host, convert into pathogenic yeasts. Emergomycosis has been described mostly as a disseminated infection, and may affect skin, lungs and other internal organs such as liver and lymph nodes (Friedman and Schwartz, 2019; Jiang *et al.*, 2018; Schwartz *et al.*, 2018). *Emergomyces* spp. was first isolated in 1994, and much of its ecology, geographical distribution and pathogenic mechanisms are still to be determined.

Introduction

Histoplasma is an endemic, thermally dimorphic fungus. It is endemic to specific regions on several continents, but epidemiology is difficult to critically assess due to a lack of systematic mandatory reporting. The major factor regulating dimorphism is temperature, with the fungus existing as a mycelium in nature or with cultivation at $\sim 25^{\circ}\text{C}$ and this mold form undergoes morphogenic transition to a yeast during infection or with culture in rich medium at $\sim 37^{\circ}\text{C}$. The mycelial form has hyphal elements that are $1.25\text{--}2.0\text{ }\mu\text{m}$ in diameter, which present tuberculate macroconidia ($\sim 8\text{--}14\text{ }\mu\text{m}$ in diameter) and microconidia ($\sim 2\text{--}6\text{ }\mu\text{m}$ in diameter), with the microconidia being the purported infectious propagule (Darling, 1909; Helmbright and Larsh, 1956). The yeast cells are typically small, slightly ovoid cells of $1\text{--}5\text{ }\mu\text{m}$ in diameter.

The American pathologist Samuel Taylor Darling reported and named histoplasmosis after the autopsy of a carpenter in Panama in 1905 (Darling, 1906, 1909), although he incorrectly determined that the microbe was a protozoan. Darling observed swollen histiocytes (thus “histo”) and plasmodium-like organisms (hence “plasma”) with what appeared to be a capsule (“capsulatum”) leading to the name *Histoplasma capsulatum*. Notably, the yeast does not in fact have a capsule. In 1912, the Brazilian investigator Henrique da Rocha-Lima correctly determined that *Histoplasma* was a fungus (da Rocha-Lima, 1912–1913; da Rocha-Lima, 1912). Recently, genome-wide population analyses have led some researchers to suggest that the genus *Histoplasma* contains at least four distinct species (Sepulveda *et al.*, 2017). However, these taxonomic changes have not been uniformly accepted, although our current chapter will generally refer to this potential group of fungi as “*Histoplasma*.”

Acquisition of *Histoplasma* may be asymptomatic and manifestations of disease range from a mild flu-like illness to life-threatening disseminated disease. The severity of this mycosis is closely associated with the quantity of the inoculum and the affected individual’s immunological state (Kauffman, 2007), with defects in cellular immunity being closely linked to disease severity. The diagnosis of histoplasmosis remains problematic, frequently resulting in delays of diagnosis. Pharmacological management requires systemic antifungal therapy, typically with a polyene or an azole, depending on disease severity. Therapy is typically several months in duration and individuals with severe immunosuppression may require life-long antifungal treatment.

Epidemiology

Histoplasmosis is reportable in 12 of the 50 states in the USA and it is only sporadically reportable in other areas of the world. *Histoplasma* is responsible for $\sim 500,000$ infections annually in the USA, making histoplasmosis the most prevalent fungal pulmonary disease (Teixeira Mde *et al.*, 2016). The areas with the highest rates of infection are in the Ohio and Mississippi River Valleys where up to 90% of individuals have acquired the fungus (Furcolow, 1963; Edwards *et al.*, 1969). A 2018 report from the USA CDC, reviewed hospitalization data from 2011 to 2014 in only 12 states (which excluded Missouri and Tennessee, states with a high incidence of *Histoplasma*) in the USA and identified 3409 cases of histoplasmosis with a 7% mortality rate (Armstrong *et al.*, 2018). The incidence of histoplasmosis was highest in geographic areas adjacent to the Mississippi River. A previous CDC report from 2016 reviewed USA hospitalizations from 2001 to 2012 and found that there were ~ 5000 admissions annually (Benedict *et al.*, 2016). Analysis of the 2002 Nationwide Inpatient Sample identified 3370 individuals with histoplasmosis with a mortality rate of 7.5% (Chu *et al.*, 2006). Hence, histoplasmosis is a consistently important pathogen in the USA, particularly in specific areas. Notably, *Histoplasma* is also being identified outside of its historic boundaries in the USA (CDC, 2013; Maiga *et al.*, 2018), possibly due to climate change.

Histoplasma is also a major killer in less developed regions of the Americas (Adenis *et al.*, 2014), particularly in Latin American countries including Brazil (Prado *et al.*, 2009; Brilhante *et al.*, 2012), Guatemala (Scheel *et al.*, 2009), and French Guiana, where it is the “first cause of AIDS-related death” (Iriart *et al.*, 2014). Notably, histoplasmosis exceeds tuberculosis in HIV infected individuals as the leading cause of death in certain regions (Adenis *et al.*, 2018; Pasqualotto and Quieroz-Telles, 2018), and it is considered an AIDS defining disease (Adenis *et al.*, 2014). Endemicity is particularly high in specific regions, such as Southeastern portions of Brazil where the prevalence is as high as $\sim 93\%$ (Guimaraes *et al.*, 2006). Although less common, *Histoplasma* is prevalent in the Caribbean, Africa, Australia and Asia (Loulergue *et al.*, 2007; Chakrabarti and Slavin, 2011; McLeod *et al.*, 2011), including newly described areas (Antinori, 2014). Moreover, given the frequency of travel, imported cases of histoplasmosis are globally reported (Bahr *et al.*, 2015).

As noted above, histoplasmosis is highly associated with advanced HIV disease, particularly once $\text{CD4} + \text{T cell}$ counts are less than $200/\text{mm}^3$ (Adenis *et al.*, 2014). Individuals receiving anti-cytokine therapies, particularly inhibition of tumor necrosis factor- α , have a high risk for histoplasmosis (Deepe, 2005). Reactivation disease arising from organ transplants, particularly liver, also may occur (Grim *et al.*, 2012).

Pathogenesis

The saprophytic mycelial form thrives in soils enriched with organic nitrogen sources, such as areas contaminated with bird or bat dropping. Disturbances of *Histoplasma* contaminated areas result in the aerosolization of conidia (Benedict and Mody, 2016). The inhaled microconidia can reach the alveoli of the lung where they undergo transformation to the yeast form (Medoff *et al.*, 1987; Allendorfer *et al.*, 1997). Early infection can be arrested by an effective immune response or the yeast cells can be captured by host effector cells and controlled within granuloma. However, during primary infection or in the setting of reactivation, the yeast can disseminate. Notably, splenic granulomas have been found on autopsy in ~70% of individuals with history of any form of histoplasmosis (Straub and Schwarz, 1955).

After recognition of *Histoplasma* by lung resident cells, neutrophils are the first recruited host effector cells to combat *Histoplasma* (Deepe *et al.*, 2008; Maza and Suzuki, 2016). Thereafter, macrophages and dendritic cells primarily engage *Histoplasma* yeast cells, where the pathogen enters into a phagosome. Activated dendritic cells and macrophages can kill *Histoplasma* (Newman *et al.*, 2006). Moreover, activation of cellular immunity is also required for control of histoplasmosis, since severe disease is more frequent in the absence of effective cellular immune responses (Allendorfer *et al.*, 1999). Th1-type cytokines are important for an effective host response, particularly IL-12 and IL-17, tumor necrosis factor- α , granulocyte macrophage colony-stimulating factor [GM-CSF], and interferon- γ (Allendorfer *et al.*, 1999). These cytokines, particularly tumor necrosis factor- α , are vital for the formation and maintenance of granuloma that control histoplasmosis.

Clinical Features

The incubation period from acquisition of *Histoplasma* to disease manifestations typically ranges from 8 to 17 days, but disease may occur within 3 days after heavy exposure (Goodwin *et al.*, 1981). The likelihood of disease is most closely linked to the infectious challenge, with low inoculum infection resulting in approximately only 1% of individuals developing self-limiting disease, whereas subclinical disease occurring in the other 99% (Pfaller and Diekema, 2010). In contrast, symptomatic disease occurs in 50%–100% of high exposures (Wheat, 1997). Fortunately, high inoculum exposures are infrequent. Hence, the vast majority of infected individuals are either asymptomatic or have mild flu-like symptoms. The most common clinical manifestation is pneumonia, although individuals may initially present with rapidly progressive, life-threatening disseminated disease involving virtually any tissue, particularly in individuals with compromised immunity. There are 3 common forms of disease: acute, disseminated and chronic.

Acute Histoplasmosis

If clinical disease manifests, it typically develops one to three weeks after acquisition (Hage *et al.*, 2008). A flu-like illness, with persistent fever, is the most common presentation. Routine laboratory and imaging is typically non-specific, although mediastinal lymphadenopathy with or without bilateral infiltrates can occasionally be observed. Acute progressive pneumonia, particularly following a heavy exposure (Kataria *et al.*, 1981), occurs in ~1 in 2000 adults (Sathapatayavongs *et al.*, 1983). Most patients with acute pulmonary histoplasmosis recover over several weeks without sequelae. Some individuals may have either a single calcified or non-calcified nodule or even a miliary (“buckshot”) pattern of calcified granulomas on subsequent chest radiographs, which can be indistinguishable from the miliary appearance of granuloma in recovered tuberculosis patients (Goodwin *et al.*, 1981).

Disseminated Histoplasmosis

In ~0.05% of individuals, *Histoplasma* yeast cells can rapidly disseminate from the lungs (Deepe *et al.*, 2008). This serious disease occurs most frequently in the setting of pre-existing immunosuppression, particularly in individuals with advanced HIV infection or cancer as well as patients on high doses of corticosteroids or cytokine-inhibitors. Subclassifications of this clinical form include acute, juvenile and chronic for respectively infants, adolescents and young adults and advanced age. Although the severity of disease can vary, fever, weight loss, and respiratory symptoms are common. Laboratory testing frequently reveals leukopenia, anemia, thrombocytopenia, abnormal liver function tests and coagulopathies (Wheat and Kauffman, 2003). Diffuse pulmonary infiltrates are present in ~70% of disseminated histoplasmosis patients (McAdams *et al.*, 1995). Disseminated disease is lethal without antifungal treatment.

Chronic Pulmonary Histoplasmosis

This disease occurs in individuals with longstanding lung diseases in which the tissue has been previously damaged. The fungus most frequently causes disease in apical bullae and the infection is characterized by progressive infiltrates, cavitation, and fibrosis (Wheat *et al.*, 1984). Diagnosis is frequently delayed (Hage *et al.*, 2012) and, without antifungal treatment, infection progresses in ~50% of affected individuals (Wheat *et al.*, 1984).

Diagnosis

The diagnosis of histoplasmosis remains problematic. Culture still stands as the gold standard, although this method requires from 1 to 4 weeks for the growth of the fungus. Unfortunately, respiratory cultures from patients with acute pulmonary histoplasmosis are positive in less than 50% of cases (Hage *et al.*, 2011b). Cultures are positive in 65%–85% of patients with chronic pulmonary histoplasmosis. Blood cultures are positive in up to 85% of patients with disseminated disease (Guimaraes *et al.*, 2006); however, yeast are usually present in bone marrow aspirates (Davies *et al.*, 1979) or can occasionally be visualized in peripheral blood (Kurtin *et al.*, 1990).

In the USA, antigen detection is commonly used in diagnosis of histoplasmosis. *Histoplasma* polysaccharide antigen can be detected in the urine of 83% with acute disease, 88% with chronic pulmonary infection and 92% of patients with disseminated histoplasmosis (Hage *et al.*, 2011b). Unfortunately, there is cross reactivity of this assay with polysaccharide of other endemic fungi (Assi *et al.*, 2011). In addition to diagnosis, these tests can be used to determine the efficacy of treatment and patient follow-up (Wheat *et al.*, 2007). In countries where the antigen detection kits are too costly, immunodiffusion tests for detection of antibodies to *Histoplasma* H and M antigens are utilized (Zancopé-Oliveira *et al.*, 1993). Antibodies are detectable by 4 weeks after infection (Williams *et al.*, 1994). Either as an alternative or for confirmation of the immunodiffusion, complement fixation tests using both *Histoplasma* antigens and intact yeast cells can also be applied for diagnosis (Wheat *et al.*, 1982). Unfortunately, these tests are less reliable in immunocompromised patients who may fail to mount antibody responses to the fungus (Bradsher, 1996).

Most recently, a lateral flow assay has been developed that may increase our ability to more widely diagnose histoplasmosis. One lateral flow assay performs similarly to the antigen detection method; however, cross reactivity with *Paracoccidioides* occurred (Caceres *et al.*, 2019).

Treatment

Treatment guidelines are currently based on the consensus of the American Thoracic Society (Limper *et al.*, 2011) and the Infectious Diseases Society of America (Wheat *et al.*, 2007). The majority of individuals who acquire *Histoplasma* do not require antifungal treatment. Unless an individual is significantly immunocompromised, those with mild, self-limited “flu-like” illnesses due to *Histoplasma* should not receive antimicrobial therapy (Wheat *et al.*, 2000). Itraconazole is the typical drug used for mild to moderate disease with the polyene amphotericin B reserved for more severe infections. Patients with chronic histoplasmosis usually require itraconazole and amphotericin B combinations for long periods (LeMonte *et al.*, 2000). Newer azoles can be used in patients not responding to itraconazole prior to the administration of amphotericin B (Perfect *et al.*, 2003; Restrepo *et al.*, 2007; Wheat *et al.*, 2006). Echinocandins should not be used to treat *Histoplasma* (Hage *et al.*, 2011a). Azole drug monitoring is important to confirm effective treatment (Andes *et al.*, 2009; Freifeld *et al.*, 2007). If available, antigen testing should be used to evaluate response to treatment.

Acute Pulmonary Histoplasmosis

Antifungal therapy is appropriate in patients with symptoms lasting more than 3 weeks. Therapy should also be given if a patient has moderate disease. Itraconazole is the recommended drug. Itraconazole should be given as a loading dose of 200 mg thrice daily for 3 days followed by 200 mg twice daily for 6–12 weeks. A new super-bioavailable itraconazole (SUIA-itraconazole) formulation has also been developed and does not have food or acid requirements that somewhat limits standard itraconazole (Fig. 1).

Moderately Severe to Severe Acute Pulmonary Histoplasmosis

Liposomal amphotericin is the preferred drug for more severe histoplasmosis (Wheat *et al.*, 2001; Johnson *et al.*, 2002). In patients with hypoxemia or significant respiratory distress, the addition of corticosteroids may be appropriate to reduce side effects in patients at risk for immune reconstitution syndromes (Breton *et al.*, 2006).

Fig. 1 *Histoplasma*. (A) The environmental form of *Histoplasma* consists of a mold form in which there are macroconidia (M, ~8–14 μm) and microconidia (m, ~2–6 μm). (B) The acquired microconidia undergo morphogenic shifts to the yeast form that reproduce by budding. (C) Yeast forms (~1–5 μm) are typically intracellular, especially in phagosomes of macrophages.

Chronic Cavitory Histoplasmosis

Itraconazole is the most commonly applied antifungal, although amphotericin should be considered for severe disease (Parker *et al.*, 1970).

Disseminated Histoplasmosis

Liposomal amphotericin is the appropriate initial drug, followed by itraconazole. The duration of therapy is typically at least a year long. A caveat is that non-immunosuppressed individuals who present with mild to moderate symptoms and are incidentally found to have disseminated disease may be treated with itraconazole alone.

Coccidioidomycosis: The Valley Fever

Hazael Hernandez, Texas Tech University Health Sciences Center, Lubbock, TX, United States

Luis R Martinez, University of Florida, Gainesville, FL, United States

Introduction

Coccidioidomycosis or valley fever is caused by *Coccidioides* species, thermally dimorphic fungi found in environmental soil that affect humans and a diversity of vertebrates (Drutz and Catanzaro, 1978a,b; Galgiani *et al.*, 2005; Smith *et al.*, 1961; Stevens, 1995; Stockamp and Thompson, 2016). This typically occurs after the inhalation of coccidioidal arthroconidia released during the perturbation of soil due to natural weather events, agriculture, land development, and recreational activities (Colson *et al.*, 2017; Nicas, 2018). There are two species (spp.) of *Coccidioides* described, *C. immitis* (Ophüls, 1905; Posadas, 1892) and *C. posadasii* (Fisher *et al.*, 2002), the latter was phenotypically described in 2002, more than 100 years after the first known case report of coccidioidomycosis was published in 1892 (Posadas, 1892).

During the 20th century, *Coccidioides* spp. emerged as a public health threat to any region with arid or semiarid conditions that support the growth of the fungus in soil as arthroconidia (Smith, 1955). The fungus is endemic of the United States (US) Southwest, Mexico, and other expansive regions of Latin America, conferring a tremendous burden onto public health systems. Tens of thousands of cases are confirmed and reported every year, with many more unidentified because of lack of testing or reporting (McCotter *et al.*, 2019). In California, coccidioidomycosis was responsible for approximately 25,000 hospitalizations and >\$2 billion dollars in hospital charges for patients during 2000–2011 (Sondermeyer *et al.*, 2013). In Mexico, the impact of coccidioidomycosis on public health is far more insidious and tragic due to their substantial agricultural workforce that is medically underserved. Upon infection or exposure, people must rely on underdeveloped health systems and lack of testing/reporting.

In the US, *Coccidioides* is reported to be encroaching on greener, more temperate territories it was never before observed in; cases are now appearing out of East Texas (Barker *et al.*, 2019) and as far north as Washington State (Marsden-Haug *et al.*, 2013). The mechanisms behind *Coccidioides*' invasive behavior are, as of yet, mysterious, but climate change might be a likely factor (Casadevall, 2019; Garcia-Solache and Casadevall, 2010). Many leading infectious disease experts have described how increasing global temperatures and the widening of the geographic ranges of thermotolerant fungi might act as a one-way highway for the expansion of fungal etiologies in the environment, and an increase in their virulence in warm human hosts (Casadevall *et al.*, 2019). Consequently, this might be an important factor in *Coccidioides*' dissemination onto newer territories.

This growing threat demands the urgent development of therapeutics and a prophylactic vaccine. Yet regardless of the irrefutable burden that *Coccidioides* causes in the present and the ominous threat it poses to our future, coccidioidomycosis, like other fungi, is relatively underrepresented in research and public attention compared to bacterial and viral agents. However, recent intensified progress has been made in the characterization of *Coccidioides* pathogenesis and vaccine development. Here, we discuss *Coccidioides* and its history up until the present, with a special emphasis on its public health significance, risk factors, and association with the environment. We then discuss the fungus' virulence factors and pathogenesis during disease. Lastly, we discuss therapeutic options and vaccination efforts.

History

Coccidioidomycosis is a significant threat to the health of millions in the western hemisphere but in 1892, the first known case report of this mycosis was published by Alejandro Posadas, an undergraduate medical student in the University Hospital Clinics (UHC) of Buenos Aires, Argentina (Posadas, 1892). His description of the skin lesions burdening 32-year old Argentine army cavalryman Domingo Ezcurra launched a century of discoveries that epitomized the scientific method and established the fungus' major players during the early 20th century; California, the US ARMY, World War II, prestigious medical institutions, and dust (Deresinski and Mirels, 2019; Hirschmann, 2007).

Early History: A Mistaken Identity

Domingo Ezcurra battled the progressive skin lesions and fevers of his disease for the next 7 years, ultimately succumbing to coccidioidomycosis in 1898. Before his passing, Posadas studied Ezcurra intensely, beginning when Dr. M. Bengolea of Rawson Hospital in San Juan, Argentina first referred Ezcurra to UHC in 1891. Bengolea had diagnosed mycosis fungoides (a cutaneous T cell lymphoma) and ordered administration of mercury and potassium iodide for 20 days, but Ezcurra's lesions were unresponsive to the treatment, thus necessitating the transfer. Previous to that, Ezcurra had been diagnosed with lupus vulgaris at an Argentine military hospital in 1889 after presenting with a verrucous lesion on his right cheek, which he believed to be a spider bite. Treatment with nitric acid in that instance did not lead to improvement and his self-administered tobacco treatment was ineffective as well.

At UHC under the supervision of Drs. Robert Wernicke and Guillermo Udaondo (Wernicke, 1892), Posadas examined Ezcurra's lesions which were progressively increasing in size and numbers. Most of Ezcurra's right cheek was covered by a fungal mass, his nose was ulcerated, and numerous papules were appearing on his extremities and trunk. Following biopsy, Posadas microscopically observed granular multinucleated giant cells with double-refractile outer envelopes. Following discussion with his mentors, Posadas believed Ezcurra's pathology had a parasitic etiology similar to microorganisms from the protozoan class *Coccidia*, a conclusion which culminated in his published case report in 1892 (Posadas, 1892).

Contemporaneous with Ezcurra's case in Argentina, the second and third documented cases emerged thousands of miles away in the US (Rixford and Gilchrist, 1896). In July 1893, farm laborer Jose Furtado Silveira was admitted to the City and County Hospital of San Francisco with an enlarging sore that began developing seven years prior in 1886, shortly after he immigrated from the Azores archipelago of Portugal (Hirschmann, 2007). In April 1894, Drs. W. S. Thorne along with Emmett Rixford of Cooper Medical College (soon to become Stanford University School of Medicine) presented Silveira's case before Californian physicians and health officials (Rixford, 1894; Thorne, 1894).

Four months later in August 1894, yet another farm laborer from the Azores, Jose Texeira Pereira, presented to St. Mary's Hospital in San Francisco with coccidioidal granuloma involving the face, where he was admitted by Drs. Thorne and L. Robinson (Hirschmann, 2007). It was now clear that Thorne and Rixford had a novel threat to public health on their hands, and they once again communicated with public health officials when they presented Pereira's case before the California Academy of Medicine. Just a few days later, Jose Texeira Pereira's condition deteriorated rapidly, and he died of coccidioidomycosis. Jose Furtado Silveira's disease progressed relatively slower (considering he first experienced symptoms in 1886) until he also succumbed to the mycosis in January 1895 (Hirschmann, 2007). Autopsy revealed tremendous dissemination as granulomas (containing the same protozoa-like, double-enveloped organisms Posadas had first observed) were found in the lungs, liver, prostate, testes, spleen, lymph nodes, adrenals, and peritoneum (Hirschmann, 2007).

While Silveira was still alive, Rixford investigated the skin as a potential portal of entry by self-inoculating Silveira with the microorganism, to no avail (Hirschmann, 2007). However, he did manage to establish subcutaneous infection in a rabbit and a dog. In collaboration with C.W. Stiles, a prominent parasitologist, Rixford published his findings with T.C. Gilchrist, a pathologist from Johns Hopkins Medical School (Rixford and Gilchrist, 1896). Together they agreed with Posada's previous findings that the etiology in question was indeed a parasite. Thus, they classified the microorganism under the new genus *Coccidioides*, and they named two different species; *immitis* (meaning "not mild") which infected Silveira, and *pyogenes* (meaning "pus-producing") which infected Pereira. Rixford and Gilchrist justified the establishment of two different species after they observed the markedly different course of disease in Silveira and Pereira, along with a difference in inflammatory processes. During their work, Rixford and Gilchrist disregarded a mysterious growth on their culture plates as a mere contaminant "mold".

It was William Ophüls, the future second dean of Stanford Medical School which would correctly establish the identity of Silveira and Pereira's infectious etiology half a decade later (Ophüls, 1905; Ophüls and Moffit, 1900). Once more, a patient with a history of immigration from the Azores and agricultural work presented to the City and County Hospital of San Francisco on January 1900, with severe disseminated coccidioidal infection. The 19-year male patient died, eleven days after admission. Upon examination of a splenic specimen from the patient, Ophüls and his collaborator Dr. Herbert C. Moffitt encountered a mysterious "white mouldy growth" similar to that which Rixford and Gilchrist had discarded during their work (Ophüls and Moffit, 1900). They also believed this to be a contaminant, but eventually proceeded to inoculate material from the Azorean patient into guinea pigs, resulting in severe disease in the animals. Microorganisms from the guinea pigs were then cultured as mycelia, and this used to infect rabbits, which developed coccidioidal nodules. This evidence led to Ophüls making his conclusion; the microorganism was not a two species parasite, but in fact was a dimorphic fungus with mycelial growth in culture that transitions into spherical bodies in mammal host tissues and reproduces by bursting into more spherules. In his publications, Ophüls delineated the life cycle of the fungus, suggested soil as a prospective reservoir, proposed its airborne route of transmission, named the disease "coccidioidal granuloma", and established the singular identity of the fungus; *Coccidioides immitis*.

No history of coccidioidomycosis is complete without mention of Dickson, Chope, Smith, and Gifford who continued to champion discovery through the 20th century. Harold Chope contracted the disease from a culture plate as a medical student in Ernest Dickson's lab, which helped establish respiration as the major route of primary infection. Charles E. Smith and Mynie Gifford dedicated much of their life to identifying the disease in the US Southwest populations and assisting the US military, which battled coccidioidomycosis on home soil during World War II. Their contributions and humanity are legendary (Hirschmann, 2020; Huntington, 1985). As one of Smith's students wrote to his widowed wife after his passing, "His is the special kind of immortality reserved for those who devote their lives to the teaching of others" (Broughton, 1967). Indeed, this sentiment can be extended to the individuals combating this disease in the past and present.

Ecology and Life Cycle of the Desert Dust Fungus

The first documented cases of coccidioidomycosis occurred in three outdoorsmen; the cavalryman Ezcurra and the agriculturalists Pereira and Silveira. This would prove to be an ominous foreshadowing of this fungus' modus operandi. Today, 17%–29% of community acquired pneumonia cases in endemic regions are attributable to *Coccidioides* (Thompson, 2011). The environmental persistence of *Coccidioides* as viable arthroconidial spores in arid/semiarid and alkaline soils is the first critical factor for its status as a medically relevant fungus in these regions (Lacy and Swatek, 1974). The fungus' tolerance of

heat and particular soil chemical characteristics demonstrate that *Coccidioides* is well adapted to regions such as the US Southwest, the Sonoran and Chihuahuan deserts of Northern Mexico, the Motagua Valley in Guatemala, as well as other Latin American arid/semiarid environments in Honduras, Brazil, Argentina, Bolivia, Colombia, Paraguay, and Venezuela (Laniado-Laborin *et al.*, 2019). Thus, the endemic range for this fungus is large, and as previously noted, seems to be expanding (McCotter *et al.*, 2019). *C. immitis* predominates in California, and *C. posadasii* everywhere else, though a few differential characteristics between these species have been established. The second critical factor is the fungus' ease of aerosolization following a disturbance of soil. Were it not for this characteristic, *Coccidioides* would rarely reach the target; a human or other mammals (and occasionally reptiles) (Del Rocio Reyes-Montes *et al.*, 2016). The fungus exists in the saprobic phase in soil as mycelia which germinate to produce barrel shaped arthroconidia that disperse quite easily, possibly in a seasonal manner involving during dry periods (Comrie, 2005; Gorris *et al.*, 2018). Perturbation of soil can result from anthropogenic or natural causes, like weather events and outdoor activities. The third critical factor is the fungus' ability to initiate a morphological and phenotypical switch to spherules upon infection, a characteristic of the thermally dimorphic fungi (Kirkland and Fierer, 2018). This transition is spurred by warm mammalian temperatures and physiological CO₂ tension, and might be enhanced due to contact with host leukocytes (Converse, 1956; Galgiani *et al.*, 1982).

Emergence of Coccidioidomycosis as a Growing Threat

In the US, the range of *Coccidioides* is expanding on multiple fronts and its threat follows right along (Gorris *et al.*, 2019). Greater amounts of cases are being reported eastwardly and valley fever has been diagnosed in workers at Dinosaur National monument, which lies in the far northern reaches of Colorado and Utah (Johnson *et al.*, 2014). Furthermore, recent cases of coccidioidomycosis in humans have been reported in south-central areas of Washington State (Marsden-Haug *et al.*, 2013). In fact, whole genome sequencing has identified highly genetically related *Coccidioides* in soil and human samples even in individuals with no travel history outside of this state (Marsden-Haug *et al.*, 2014; Oltean *et al.*, 2019). In addition, many animals in Washington State have tested positive for coccidioidomycosis (James *et al.*, 2019). This strong evidence indicates that Washington State is in the fungus' endemic range, and nearby states such as Idaho, Montana, Oregon, and Wyoming might soon prove to be as well. Moreover, *Coccidioides* DNA has been isolated from Oregon soil (Benedict *et al.*, 2018). Global warming is the hypothesized driver of fungal proliferation in the environment, as climate change expands arid/semi-arid geography and might put selective pressure on fungi to better survive in regions with warmer temperatures (Casadevall *et al.*, 2019).

Coccidioidomycosis is a Threat to Public Health in the Western Hemisphere

Risk Factors

Ophüls was the first to speculate on *Coccidioides* association with the environment and a century of research since then has given us great insight into the corresponding risk factors. It is now clear that anyone with environmental exposure in endemic areas is potentially at risk, even healthy individuals without immunodeficiency, albeit rarely (Pearson *et al.*, 2019). Involvement in construction (Laws *et al.*, 2018), archeology (Johnson *et al.*, 2014), field expeditions, military field exercises (Crum-Cianflone, 2007), agriculture (Levan and Huntington, 1965), sports (Stern and Galgiani, 2010), hunting (Brillhante *et al.*, 2012), and a multitude of other outdoor/recreational activities can result in infection (Diaz, 2018). Prison populations are of particular concern as very high rates of coccidioidomycosis among incarcerated individuals have been observed on multiple occasions (Lee *et al.*, 2017). In California, the cost in correctional health services due to coccidioidomycosis was \$23 million from 2006 to 2010 (Lee *et al.*, 2017).

Travel to endemic regions also presents risks of exposure (Diaz, 2018). US Southwest states are world hubs for tourism and they experience vast amounts of incoming travel, as do many endemic regions in Latin America. This has resulted in a significant incidence of coccidioidomycosis outside of endemic zones (Panackal *et al.*, 2002). Hundreds of cases in Canada, Asia, Europe, and Australia have also been well documented, and it is likely many have remained undiagnosed due to the self-resolving nature of the disease and the multitude of illnesses with similar manifestations. Clinicians around the world should be alert and consider coccidioidomycosis in the differential diagnosis in individuals who present with a travel history to endemic regions.

Non-environmental risk factors have also been characterized. For example, pregnancy is one of the most common risk factors for disseminated coccidioidomycosis (Bercovitch *et al.*, 2011). Men display a predisposition to coccidioidomycosis, and they experience a higher rate of infection and dissemination, as do non-Caucasians such as Hispanics, African Americans, and Filipinos (Louie *et al.*, 1999; Ruddy *et al.*, 2011). Furthermore, Alaskan Natives and American Indians experience high morbidity and hospitalization rates, a racial tendency that is unique to *Coccidioides* (McCotter *et al.*, 2019). The fungus is also opportunistic in HIV/AIDS patients and patients with low CD4⁺ T-cell population are particularly at risk of disseminated coccidioidomycosis (Kirkland and Fierer, 2018; Ampel *et al.*, 1993). Moreover, individuals with immunosuppression associated to organ transplants, corticosteroid therapy, and treatment with TNF- α antagonists result in greater risk (Bergstrom *et al.*, 2004; Blair and Logan, 2001; Brown *et al.*, 2013). People with chronic conditions such as diabetes and cardiopulmonary disease are also highly susceptible to valley fever (Rempe *et al.*, 2007).

Clinical Manifestations

The incubation period of *Coccidioides* can range from one to four weeks post-infection and 60%–65% of primary infections remain asymptomatic. Individuals with symptomatic infections typically present with usual signs and symptoms caused by respiratory infections such as fever, night sweats, myalgia, arthralgia, headache. These manifestations can be accompanied by pneumonia, in which case the syndrome is classified as community acquired pneumonia. Although not exclusively, pneumonia can resolve in immunocompetent individuals without medical intervention or therapy. Within the first few days of illness, 10%–30% of individuals can also experience non-specific diffuse erythematous rash on the trunk and extremities that typically disappears shortly thereafter (Cox and Magee, 2004).

Radiographic imaging is instrumental in assessing the extent of coccidioidomycosis progression in the lungs. In <5% of cases, a persistent pulmonary infection develops resulting in progressive pneumonia accompanied by pulmonary nodules and cavities (Cox and Magee, 2004). Further complications can include hemorrhage, secondary infections, and pulmonary lesions. Disseminated disease occurs in <1% of cases and meningitis is the most serious form of systemic disease. Usually ~90% of individuals with coccidioidal meningitis die within a year and 100% within 2 years (Cox and Magee, 2004). The fungus can also disseminate cutaneously and to other organs. In very rare cases, patients might exhibit primary cutaneous coccidioidomycosis (Shiu *et al.*, 2018), though prognosis for this is excellent and the infection typically resolves with proper treatment.

Coccidioides in the US Southwest

Primary respiratory coccidioidomycosis is colloquially referred to as Valley Fever in some regions of the US Southwest where the disease remains a leading cause of community acquired pneumonia. More than 25% of the US population lives in this region, which puts more than 80 million citizens within the reach of *Coccidioides*. California, Arizona, Nevada, Utah, New Mexico, and Texas are all endemic to varying degrees and, as noted earlier, experts and leading health authorities agree that the fungus' endemic range seems to be expanding. Moreover, millions of older individuals retire to this US region, causing preoccupation about their ability to deal with this infection particularly for those who have never been previously exposed to *Coccidioides* (Benedict *et al.*, 2018). In California, 75% of cases occur in the San Joaquin Central Valley (Dizon *et al.*, 2019) and one estimate placed the average financial burden of Californian patients who sought medical attention at \$57,000 (Wilson *et al.*, 2019). Patients with disseminated diseases incurred on average \$1,000,000 in costs, while patients with uncomplicated and diffuse pneumonia spent between \$22,000 and \$132,000, respectively (Wilson *et al.*, 2019). Additionally, 90% of people with disseminated disease lose an average of 90 days of work whereas 10% leave the workforce permanently (Wilson *et al.*, 2019). Arizona also faces similar severe healthcare and economic burden due to coccidioidomycosis (Hector *et al.*, 2011).

Reported cases of coccidioidomycosis in the US decreased steadily from 2011 (22,641 cases) to 2014 (8232 cases), although there has been a recent surge in the number of cases with 15,611 cases documented in 2018 (Anon1). Domesticated and wild animals are also highly susceptible to coccidioidomycosis. For example, dogs are particularly vulnerable with 6%–10% of canine in Arizona's "Valley Fever Corridor" affected, corresponding to 60,000 yearly infections and \$1000 per animal in veterinary costs (Anon2; Anon3). Close to 25% of canine coccidioidomycosis becomes complicated and may result in additional costs for owners.

Interestingly, dust storms and natural disasters are important drivers of coccidioidomycosis outbreaks (Hernandez and Martinez, 2018; Tong *et al.*, 2017). In 1977, a dust storm in the San Joaquin Valley was the cause of hundreds of cases across Sacramento, a US Navy air Station in Kings County, and many other Californian counties (Flynn *et al.*, 1979; Williams *et al.*, 1979). In 1994, 204 cases were associated to a 6.7 magnitude earthquake in Northridge, California that produced formidable dust clouds (Schneider *et al.*, 1997). Since the frequency of dust storms and other natural disasters has increased in the past few decades, these have been correlated with increased valley fever cases.

Coccidioides in Latin America

Regions with ecological features conducive to coccidioidal proliferation are widespread in Latin America. Yet, clinical and epidemiological data of coccidioidomycosis is limited due to the underdeveloped health systems predominating in many areas. Although there have been surveys conducted to assess the prevalence of coccidioidomycosis, much of the data is outdated and unconsolidated, even within individual countries. The lack of knowledge about this infection's true impact is especially worrying in Latin America, since there are so many rural communities whose livelihoods depend on agriculture. Despite the widespread occupational hazard coccidioidomycosis presents, awareness amongst the general public remains low, and diagnostic resources are often unavailable, which exacerbates underreporting and improper cataloging of cases. Furthermore, patients often lack the financial means to access proper treatment.

Coccidioides is particularly well studied in Mexico since the fungus' initial detection in the 1940s (Madrid, 1946, 1948) and majorly endemic of the northern states bordering the US Southwest (Laniado-Laborin *et al.*, 2019; Kirkland and Fierer, 2018). The climate and soil conditions in these states are similar to those in the US Southwest and they provide an adequate ecological niche for the fungus. Up to its dismissal as a reportable disease in 1994, an average of 1,500 cases were reported yearly in Mexico (Laniado-Laborin *et al.*, 2019). Although clinical data has been sparse since then, incidence in Mexico is likely to be the highest amongst Latin American nations as many estimates place statistics on par with the US endemic areas (Ajello, 1967). *Coccidioides*

antigen testing among Mexican populations have consistently demonstrated high infection rates and one particular study from the state of Coahuila revealed a 93% exposure rate within the local residents (Mondragon-Gonzalez *et al.*, 2005).

Central and South America have been less extensively studied and documented autochthonous cases are scarce. However, animal and human cases have been described since the mid 20th century and surveys have shown high reactivity rates in certain regions. In Central America, the majority of data indicates that *Coccidioides* is endemic to some degree in Honduras and Guatemala, specifically in the Motagua Valley as evidenced by a skin test survey of approximately 10,000 individuals (Laniado-Laborin *et al.*, 2019; Mayorga and Espinoza, 1970). The first case in Honduras was described in 1951 (Castro and Trejos, 1951), while Guatemala's first case was reported in 1960 (Garcia Valdes *et al.*, 1960). In South America, less than 1,000 cases have been reported to date in Colombia, Venezuela, Brazil, Paraguay, Bolivia and Argentina (Laniado-Laborin *et al.*, 2019). Over 800 of those cases have been found in Brazil (Giacomazzi *et al.*, 2016), but these statistics are likely confounded by factors such as underreporting, misdiagnosis, lack of access to care, underrepresentation in research, and lack of awareness. Antigen reactivity surveys have demonstrated a significant infection rate in the majority of these South American countries (ranging from 2% to 40%) given that the optimal ecological conditions for the fungus' growth and survival are present. Therefore, it is likely that a combination of the above confounding factors prevents the true scale of this disease in Latin America to be known.

Virulence and Pathogenesis

Respiration is the major avenue of entry into the body for coccidioidal arthroconidia. Once inhaled, arthroconidia (<5 µm in size) differentiate into spherules within the first few days of infection. Spherules are the multinucleated giant cells described by Posadas, Rixford, and Ophüls in their early investigations. The dose of arthroconidia inoculum required to initiate a progressive infection in humans is not well-known, but as few as 10–50 spores have been shown to cause disease in non-human primates (and other animal models) in less than 4–6 weeks post-challenge (Blundell *et al.*, 1961; Converse *et al.*, 1962). Spherules enlarge and segment endogenously until they achieve maturity (15–120 µm diameter) followed by rupture (endosporulation) which releases hundreds of endospores (<10 µm diameter). These endospores grow isotopically and mature themselves into 2nd generation endosporulating spherules thereby repeating the parasitic life cycle and propagating the infection.

As is the case with most foreign bodies in the alveolar space, host innate immune responses, specifically phagocytosis, are critical for clearance. Resident alveolar macrophages are appropriately sized to phagocytize arthroconidia, initial immature spherules, and endospores, but they are much too small to dispose of mature spherules (Castro-Lopez and Hung, 2017; Van Dyke *et al.*, 2019). Upon endosporulation, a chemotactic neutrophil response is mounted by the host and neutrophils are appropriately sized to clear initial spherules and endospores (Drutz and Huppert, 1983; Galgiani *et al.*, 1978). However, phagocytic cells such as macrophages and neutrophils are insufficient to clear the infection alone. *Coccidioides* can escape engulfment (Drutz and Huppert, 1983), prevent phagocytosis (Lee *et al.*, 2015), and inhibit phagolysosomal fusion (Lewis *et al.*, 2015). The role of neutrophils in response to coccidioidal infection is not well understood and appears to be complex and sometimes contradictory in nature. One study revealed similar susceptibility between neutrophil deficient mice and control mice to coccidioidal challenge, indicating that neutrophils play a limited role in the immune response to this fungus (Hung *et al.*, 2014). Further research is needed to fully elucidate neutrophil mechanisms and their effect on coccidioidomycosis, but it is likely that associated inflammatory responses and their modulation during coccidioidal infection are key in determining host outcomes (Van Dyke *et al.*, 2019).

As spherules mature, a membranous layer termed the spherule-outer wall (SOW) develops and sheds (Cole *et al.*, 1988a). A particular glycoprotein within this fraction (SOWgp) has been established as the immunodominant molecule as it exhibits high immunoreactivity to anti-coccidioidal antibodies isolated from patients (Cole *et al.*, 1988b; Hung *et al.*, 2000; Hung *et al.*, 2002). Interestingly, there is evidence that SOWgp is also a coccidioidal adhesin, possibly mediating the fungus' binding to respiratory tissues through ligands like laminin, fibronectin, and/or collagen (Hung *et al.*, 2002). For example, 58% of mice challenged with a SOWgp knockout strain of *C. immitis* survived beyond 40 days post-challenge while none of the mice challenged with wild type *C. immitis* survived longer than 21 days. Furthermore, the SOWgp mutant strain demonstrated a 30%–50% reduction in its ability to bind fibronectin and laminin *in vitro*. SOWgp contains characteristic tandem repeats of proline/aspartate motifs (Hung *et al.*, 2007), and concerted evolution of these sequences is a proposed mechanism for the ability of the fungus to evade host immune responses during release (Johannesson *et al.*, 2005). There is also evidence that proline-rich region are key motifs in other proteins that participate in adhesion of microbes to host tissues, suggesting the role of SOWgp as an adhesin (Hung *et al.*, 2002; Brady *et al.*, 1998; Perfect *et al.*, 1998; Staab *et al.*, 1999).

Coccidioides modulates the expression of SOWgp during different stages of its parasitic life cycle as copious amounts are synthesized and shed during maturation but much less so during endosporulation, when *Coccidioides* is most vulnerable to the host response, especially phagocytosis (Hung *et al.*, 2002). In addition, the fungus releases a metalloproteinase (Mep1) (Hung *et al.*, 2005) that digests SOWgp, lowering opsonization and conferring a higher degree of evasion potential to the endospores during this critical time (Hung *et al.*, 2005). Mice immunized with recombinant SOWgp and challenged with a Mep1 deficient *C. Posadasii* strain exhibited significantly increased survival compared to mice challenged with a wild type strain (Hung *et al.*, 2005).

The extracellular release and accumulation of ammonia during infection is also a proposed *Coccidioides* virulence mechanism, similar to what is observed in *Helicobacter pylori* infection (Mirbod-Donovan *et al.*, 2006; Mobley, 1996; Wise *et al.*, 2013). Endogenous coccidioidal urease and likely ureidoglycolate hydrolase catalyze the formation of ammonia in culture, the environment, and host tissues in order to increase the pH (Mirbod-Donovan *et al.*, 2006; Mirbod *et al.*, 2002; Yu *et al.*, 1997). The

accumulation of ammonia increases the alkalinity of infection microenvironments in the lung, resulting in localized tissue damage and exacerbation of respiratory disease. For instance, a urease deficient *C. posadasii* strain was less virulent to mice than the wild type strain (Mirbod-Donovan *et al.*, 2006; Wise *et al.*, 2013).

Coccidioides can produce melanin (Nosanchuk *et al.*, 2007) and this pigment confers protection against antifungal drugs, UV light, toxic metals, and other environmental stresses (Nosanchuk and Casadevall, 2003). However, limited information on *Coccidioides* melanization is available and further studies are needed.

Treatment and Prevention

The majority of patients with coccidioidomycosis have a subclinical infection and in many cases the disease can resolve on its own. There is no an effective therapy that results in resolution of coccidioidomycosis in all manifestations of the disease. There is also no data arising from randomized, double blinded, placebo controlled clinical trials on the decision to treat primary pulmonary infection. Therefore, current and past practice guidelines suggest a highly individualized treatment plan for patients (Galgiani *et al.*, 2005, 2016a, 2000). Administration of therapeutics is usually not recommended in immunocompetent patients with uncomplicated primary respiratory infection (uncomplicated pneumonia, asymptomatic nodule or cavity). However, patient health education, periodic reassessment of symptoms, and radiographic findings is highly encouraged. Disease related complications (diffuse bilateral pneumonia, symptomatic/ruptured pulmonary cavity, chronic progressive fibrocavitary pneumonia, meningeal/non meningeal dissemination) typically warrants antifungal therapy and possible surgical intervention. Antifungal therapy is typically long (many months to years) and might be indefinite or lifelong varying from case to case basis.

Therapeutics

The pharmacology and treatment of coccidioidomycosis has been comprehensively reviewed (Thompson *et al.*, 2019). Azole and polyene classes of antifungal drugs are the most common therapeutics used against coccidioidomycosis. Due to the variable toxicity and pharmacological profiles of these options, an individualized approach is highly emphasized in every treatment guideline (Thompson *et al.*, 2019). Fluconazole, for example, is the most frequently prescribed drug for coccidioidomycosis. This antifungal drug is low cost, has high bioavailability, is highly tolerable, distributes well into tissues, and can be administered orally or intravenously. This is especially important when treating central nervous system (CNS) disseminated coccidioidomycosis (Arndt *et al.*, 1988; Felton *et al.*, 2014). In contrast, itraconazole becomes highly protein bound in plasma and exhibits extremely low cerebrospinal fluid (CSF) and bone penetration. Despite this, treatment with itraconazole has shown efficacy in animal and clinical coccidioid meningitis. Moreover, an enhanced response rate in patients treated with itraconazole demonstrated in comparison to fluconazole. Additional clinical data is needed to fully understand whether itraconazole is a more efficacious treatment in the setting of cerebral fungal infection.

Voriconazole is often utilized when patients become intolerant or refractory to fluconazole or itraconazole. The therapeutic exhibits less protein binding than itraconazole and an approximately proportional increase in CSF penetration also demonstrating efficacy in controlling dissemination to the CNS. All azole drugs typically exhibit some degree of hepatotoxicity, however, the concerns for toxicity as well as to drug-drug interactions are elevated for voriconazole (Thompson *et al.*, 2019; Freifeld *et al.*, 2009; Kim *et al.*, 2011). Posaconazole is another option for the treatment of refractory cases, despite its reduced CSF penetration. This drug has demonstrated promising sterilization in animal tissues, although data concerning this therapeutic is limited (Thompson *et al.*, 2019; Gonzalez *et al.*, 2002; Lutz *et al.*, 1997).

Before the advent of the azoles, amphotericin B was widely used in the treatment of coccidioidomycosis. Today and due to its high toxicity (Thompson *et al.*, 2019; Sawaya *et al.*, 1991), it is usually reserved for severe cases or for patients who are refractory or intolerant to other therapies (Thompson *et al.*, 2019; Galgiani *et al.*, 2016b). Amphotericin B also has poor penetration into the CNS when administered intravenously. Intrathecal delivery is an option but requires specialized training which can be unavailable to many patients suffering from coccidioid meningitis.

Prophylaxis and Vaccination

There is little to no evidence supporting prophylactic therapeutic use to prevent *Coccidioides* infection. However, a future vaccination option is likely because resolved coccidioidomycosis typically confers lifelong immunity to individuals that recovered from the disease. One of the first vaccine candidates (which proceeded to a phase III trial) was investigated in the 1960s when mice were immunized with formalin-killed spherules (FKS) (Levine *et al.*, 1960). Ultimately, the vaccine did not confer as much protection as anticipated and it induced an over reactive immune response in patients enrolled in a clinical trial (Pappagianis, 1993). Recent attempts at developing live attenuated vaccines have particularly focused on disrupting the chitinase (CTS₂ and CTS₃; ΔT vaccine) (Xue *et al.*, 2009) and CPS₁ (a chitinase homolog; ΔCPS₁ vaccine) genes (Narra *et al.*, 2016) in *Coccidioides*. Both have shown efficacy in murine models and ΔCPS₁ is currently being developed as a vaccine for dogs (Narra *et al.*, 2016; Shubitz *et al.*, 2018). The ΔT vaccine candidate has also helped to understand the importance of Th1 and Th17 mediated immunity in achieving robust protection against *Coccidioides* (Hung *et al.*, 2011). However, live attenuated strains must display absolute safety in humans

especially in immunocompromised individuals, and there remains much work to be performed before this type, or indeed any vaccine proceeds to be use for human prophylaxis. It is important to note that the US Food and Drug Administration have never approved a live attenuated eukaryotic vaccine.

With the advent of recombinant technology, many vaccine efforts have targeted the use of recombinant spherule-derived antigens. Of these, antigen 2/proline rich antigen (Ag2/PRA), a component of a coccidioidal glycoprotein, has been the most extensively studied (Cox and Magee, 2004). *Coccidioides*-specific antigen (Csa) and peroxisomal matrix protein 1 (Pmp1) have also shown promise (Castro-Lopez and Hung, 2017; Van Dyke *et al.*, 2019). Although they all show individual promise, it has been proposed that a multivalent vaccine containing a number of these recombinant antigens will be necessary to elicit a protective immune response. Leading adjuvant and delivery system candidates are EP67 (Hung *et al.*, 2012), dendritic cells (Awasthi *et al.*, 2005; Awasthi *et al.*, 2019), and glucan particles (Hung *et al.*, 2018; Hurtgen *et al.*, 2012). It is likely that an effective vaccine will utilize such an adjuvant alongside an attenuated strain or multiple recombinant antigen vaccine to elicit a Th1 and Th17 immune response (Castro-Lopez and Hung, 2017; Van Dyke *et al.*, 2019).

Authorship

Both authors contributed to the writing of the manuscript.

Conflict of Interest

The authors declare no conflict of interest.

Blastomyces and Blastomycosis

Bruce S Klein, Joseph A McBride, and Gregory M Gauthier, University of Wisconsin, Madison, WI, United States

© 2021 Elsevier Inc. All rights reserved.

Overview

The *Blastomyces* species complex belongs to a group of fungi whose dominant biologic feature is thermal dimorphism, which is the ability to switch between hyphae (22–25°C) and yeast (37°C) (Gauthier, 2015). Currently, there are 7 species of *Blastomyces*: *B. dermatitidis*, *B. gilchristii*, *B. persicus*, *B. helicus*, *B. parvus*, *B. silvae*, and *B. emzantsi*. (Brown *et al.*, 2013; Muñoz *et al.*, 2015; Dukik *et al.*, 2017; Schwartz *et al.*, 2019; Jiang *et al.*, 2018; Maphanga *et al.*, 2020). Infection is acquired via inhalation of aerosolized conidia or hyphal fragments into the lung following spore soil disruption. Once inhaled into the lungs, these infectious particles convert into pathogenic yeast to cause pneumonia. A subset of patients with pneumonia will develop disseminated infection. Diagnosing *Blastomyces* infection and initiating antifungal therapy in a timely manner can be difficult because blastomycosis mimics other infectious and non-infectious diseases (McBride *et al.*, 2017). A combination of fungal staining, fungal culture, and non-culture based tests are used for diagnosis (Saccante and Woods, 2010). Polyene and triazole antifungals are used for treatment (Chapman *et al.*, 2008; Limper *et al.*, 2011; Miller *et al.*, 2019).

Historical Perspective

Blastomycosis was first described as a cutaneous disease in 1894 by Thomas Gilchrist and was initially thought to be a protozoan infection (Gilchrist, 1894). Additional research by Drs. Gilchrist and Stokes correctly identified the etiologic agent as a fungus, which was named *Blastomyces dermatitidis* (Gilchrist, 1896; Gilchrist and Stokes, 1896, 1898). The ability for *B. dermatitidis* to switch between mycelia and yeast forms in response to temperature was discovered in 1907 (Hamburger, 1907). In the early 20th century, pulmonary and disseminated blastomycosis was described. Colloquial names for blastomycosis included “Gilchrist Disease”, “Chicago Disease”, and “North American Blastomycosis”. In the early 1950s, the lung was determined to be the primary portal of entry for infection (Schwarz and Baum, 1951). The first recognized outbreak of blastomycosis occurred in Grifton, North Carolina (1953–1954) (Smith *et al.*, 1955). In the mid-1980s, successful culture of *Blastomyces* from the soil in Eagle River, WI and Tomorrow River, WI in association with human outbreaks helped define the incubation period and ecologic niche (Klein *et al.*, 1986a, 1987a). Clinical trials conducted in the 1990s assessed the efficacy of itraconazole and fluconazole for treatment of blastomycosis (Pappas *et al.*, 1995, 1997; Dismukes *et al.*, 1992). Practice guidelines for blastomycosis were first published by the Infectious Diseases Society of America (IDSA) in 2000 and updated in 2008 (Chapman *et al.*, 2008, 2000). In 2011, the American Thoracic Society (ATS) Fungal Working Group published blastomycosis treatment guidelines in 2011 (Limper *et al.*, 2011). The American Society of Transplantation (AST) published their guidelines on the management of blastomycosis in transplant recipients in 2019 (Miller *et al.*, 2019).

Mycology and Phylogenetics

Blastomyces and other thermally dimorphic fungi such as *Emergomyces*, *Histoplasma*, *Coccidioides*, *Paracoccidioides*, *Sporothrix*, and *Talaromyces marneffei* (formerly *Penicillium marneffei*) belong to the Ascomycota phylum (Sil and Andrianopoulos, 2014). *Blastomyces* is a complex of 7 species: *B. dermatitidis*, *B. gilchristii*, *B. persicus*, *B. helicus* (formerly *Emmonsia helicus*), *B. parvus* (formerly *Emmonsia parvus*), *B. silvae*, and *B. emzantsi* (Brown *et al.*, 2013; Muñoz *et al.*, 2015; Dukik *et al.*, 2017; Schwartz *et al.*, 2019; Jiang *et al.*, 2018; Maphanga *et al.*, 2020). *B. dermatitidis* and *B. gilchristii* are estimated to have diverged 1.9 million years ago during the Pleistocene epoch (McTaggart *et al.*, 2016). *B. gilchristii* was named in honor of Dr. Gilchrist, who first described blastomycosis in the medical literature (Gilchrist, 1894). *Blastomyces silvae* was named after Eleanor Silver Keeping (née Dowding), a mycologist at the University of Alberta (Jiang *et al.*, 2018). The genomes of *B. dermatitidis*, *B. gilchristii*, and *B. persicus* have been sequenced and are publicly available (Muñoz *et al.*, 2015; see “Relevant Website section”). *B. dermatitidis* and *B. gilchristii* contain 9180–10,187 genes and have a genome size of 66.6–75.4 MB, which is 2-fold larger than closely-related fungi such as *H. capsulatum* (Muñoz *et al.*, 2015). *B. persicus* has a similar number of genes but a smaller genome size, 32.3 MB (Dukik *et al.*, 2017). The genomes of *B. helicus*, *B. parvus*, and *B. silvae* have yet to be sequenced. Regardless of species, the defining biologic feature of these fungi is thermal dimorphism, the ability to reversibly convert between hyphal and yeast forms in response to temperature shifts (Gauthier, 2015).

In the environment (22–25°C), *Blastomyces* species grow as septated hyphae (1–2 µm diameter) with conidiophores that each bear a single conidium (4–5 µm) (Fig. 1(A); Winn *et al.*, 2006; Wolf *et al.*, 1975). *B. persicus* conidiophores can bear single or multiple conidia (Dukik *et al.*, 2017). *B. helicus* hyphae have a unique coiled appearance and fail to produce conidia under most in vitro conditions (Schwartz *et al.*, 2019).

At 37°C, *Blastomyces* cells grow as yeast that are typically 8–20 µm in size with a doubly refractile cell wall and an average of 3–4 nuclei per cell (Fig. 1(B); Saccante and Woods, 2010; Winn *et al.*, 2006; Wolf *et al.*, 1975; Clemons *et al.*, 1991). *Blastomyces* yeast

Fig. 1 Hyphal and Yeast forms of *Blastomyces dermatitidis*. (A) hyphal form with conidia at 22°C. (B) Yeast form at 37°C. Arrow points to broad-based budding between mother and daughter cells. Scale bar = 10 μ m. Figure was modified from Gauthier, G.M., Klein, B.S., 2020. Chapter 264, Blastomycosis. In: Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases, ninth ed., vol. 2. Philadelphia, PA: Elsevier.

exhibit a broad-based pattern of budding between daughter and mother cells. This unique budding pattern allows *Blastomyces* yeast to be distinguished from other fungal pathogens (Saccante and Woods, 2010). In clinical medicine, *B. dermatitidis* and *B. gilchristii* are the 2 most commonly encountered agents of *Blastomyces*. These species are morphologically similar under light microscopy and differentiation requires PCR analysis or DNA sequencing (C for *B. gilchristii* and T for *B. dermatitidis* at base-pair 19 in the untranslated region of ITS2) (Brown *et al.*, 2013; Meece *et al.*, 2010; Frost *et al.*, 2016). *B. helicus* also has a broad-based budding pattern and sequencing of the ITS (internal transcribed spacer) or D1/D2 domains of the long subunit of ribosomal RNA can provide definitive identification (Schwartz *et al.*, 2019).

Although there is an ongoing effort to simplify fungal nomenclature (e.g., one fungus = one name), a dual nomenclature system is used with one name for the asexual form and another for sexual form (Taylor, 2011). *Blastomyces* refers to the asexual form and *Ajellomyces* refers to the sexual form (Li *et al.*, 2013; McDonough and Lewis, 1967). Asexual or clonal reproduction involves hyphal growth, production of asexual spores known as conidia, and yeast cell division. Sexual reproduction only occurs in the hyphal phase in which the hyphae of opposite mating types (+ and –) fuse to form mating structures (cleistothecia) for exchange of genetic material and development of ascospores (Li *et al.*, 2013; McDonough and Lewis, 1967). This is known as heterothallic mating. Homothallic or self mating has not been described. Typically, *B. dermatitidis* mates with *B. dermatitidis* and *B. gilchristii* mates with *B. gilchristii*; however, recent genotyping analyses suggest the potential for mating to occur between *B. dermatitidis* and *B. gilchristii* (Frost *et al.*, 2016; Li *et al.*, 2013). From a genetic perspective, the “+” mating type cells have the α -box gene and “–” mating type cells contain the HMG gene (Li *et al.*, 2013).

Geography and Ecology of *Blastomyces*

Blastomycosis has been reported from 3 continents including North America, Africa, and Asia (Fig. 2). In North America, *Blastomyces* is not uniformly distributed, rather it is restricted to specific ecological niches within the endemic region. *B. dermatitidis* has the widest geographic distribution in North America which includes U.S. states located in watersheds of the Mississippi river, Ohio river, Savannah river, Saint Lawrence river, and areas adjacent to the Great Lakes (Fig. 2(A); McTaggart *et al.*, 2016). In Canada, *B. dermatitidis* has been identified in several provinces around the Nelson river and St. Lawrence river watersheds, the Great Lakes, and Saskatchewan (McTaggart *et al.*, 2016). In contrast, *B. gilchristii* has a more restricted distribution and overlaps with *B. dermatitidis* in Canada, Minnesota, Wisconsin and New York (Fig. 2(A); McTaggart *et al.*, 2016). The differences in geographic distribution between *B. dermatitidis* and *B. gilchristii* are hypothesized to be related to differences in glaciation in the Pleistocene epoch, which was when *B. dermatitidis* and *B. gilchristii* diverged, approximately 1.9 million years ago (McTaggart *et al.*, 2016). *B. gilchristii* is restricted to formerly glaciated areas (McTaggart *et al.*, 2016). The ecologic niche inhabited by *B. dermatitidis* and *B. gilchristii* is characterized by sandy soils with an acidic pH and decaying vegetation that are nearby waterways (Klein *et al.*, 1986a,b; Klein *et al.*, 1987a,b; Reed *et al.*, 2008). *B. helicus* has been isolated from humans and animals in the Western United States (California, Montana, Idaho, Colorado, Nebraska, Texas) and Canada (Saskatchewan, Alberta) (Fig. 2(A); Schwartz *et al.*, 2019). *B. helicus* does not appear to overlap with the endemic regions for *B. dermatitidis* or *B. gilchristii* (Schwartz *et al.*, 2019). *B. silverae* isolates have been from the U.S. or Canada; however, the endemic range has yet to be fully elucidated (Jiang *et al.*, 2018). The characteristics of specific ecological niche inhabited by *B. helicus* and *B. silverae* are unknown.

Outside of North America, autochthonous culture-proven cases of blastomycosis have been reported from Africa, India, and Israel (Fig. 2(B)). Approximately 100 human cases of blastomycosis have been reported from 18 African countries (Baily *et al.*, 1991; Carman *et al.*, 1989). The majority of these isolates were identified before phylogenetic reclassification and have not undergone molecular analysis or sequencing. Thus, the majority of these isolates have been presumptively classified as *B. dermatitidis*; however, a recent study suggests that many African *Blastomyces* isolates may be *B. percursor* or *B. emzantsi* (Maphanga *et al.*, 2020). African *Blastomyces* stains have a decreased capacity to transition to yeast at 37°C, possess unique media requirements for growth, and possess a less antigenically complex cell surface (Klein *et al.*, 1997). *B. percursor* has been cultured from humans in South Africa

Fig. 2 Geographic distribution of *Blastomyces*. (A) Endemic regions of *B. dermatitidis*, *B. gilchristii*, and *B. helicus* in North America. (B) Geographic range of *Blastomyces* outside of North America. Because the endemic regions for *Blastomyces* spp. in Africa, India, and Israel are unknown, whole countries were shaded for illustrative purposes.

and Israel (Dukik *et al.*, 2017). In India, less than 10 culture-confirmed autochthonous cases of blastomycosis have been reported (Rao *et al.*, 2013; Randhawa *et al.*, 2013). The characteristics that define the ecologic niche for *Blastomyces* species in Africa and Asia is unknown. *Blastomyces* is not endemic to Central America, South America, Europe, or Australia.

Epidemiology

The absence of reliable skin and serologic tests to investigate *Blastomyces* exposure in populations living in endemic and non-endemic regions has limited the epidemiologic understanding of blastomycosis to persons with clinically apparent infection. Minnesota, Wisconsin, Michigan, Arkansas and Louisiana require mandatory reporting of human blastomycosis. In Canada, blastomycosis is reportable in Manitoba and confirmed human cases in Ontario are monitored by the Northwestern Health Unit jurisdiction. Outside of the United States and Canada, the epidemiology of blastomycosis is unknown.

Within the endemic region for *B. dermatitidis* and *B. gilchristii*, the annual incidence ranges from 0.11 to 2.17 cases/100,000 persons with the highest rates in the Midwest and Southern United states (Table 1). Within the endemic region, certain areas are hyperendemic for blastomycosis such as Vilas County in Wisconsin and Kenora in Ontario (Baumgardner *et al.*, 1992; Dwight *et al.*, 2000). Although the majority of blastomycosis cases are sporadic, urban and rural outbreaks have been reported from 7 states and are associated with activities that disrupt soil such as construction or fresh water recreation (Table 2). Outbreak investigations have been critical defining the ecologic niche in North America, delineating the risk for symptomatic infection following exposure (approximately 50% develop symptoms), determining the incubation period (3 weeks – 3 months), and understanding environmental risk factors for blastomycosis (Table 2; Klein *et al.*, 1986a, 1987a). Outbreaks of blastomycosis in Marathon County, WI in 2006 and 2009–2010 found high rates of symptomatic blastomycosis in persons of Hmong ethnicity (odds ratio 12.1; 95% confidence interval 1.3–611.9; $p = 0.019$) that was unrelated to environmental exposure (Roy *et al.*, 2013). The frequency of disseminated blastomycosis was not increased in persons of Hmong ethnicity during these outbreaks (Roy *et al.*, 2013). This novel and unexpected finding was hypothesized to be related to an immunologic predisposition for infection (Roy *et al.*, 2013). An increased incidence of blastomycosis has also been described for indigenous persons living in Ontario and Manitoba (Crampton *et al.*, 2002; Dalcin and Ahmed, 2015; Kralt *et al.*, 2009).

Pathogenesis, Virulence, and Host Defense

Overview

Relatively few of the estimated 1.5–5.1 million fungal species are known to cause invasive infection in humans or animals (Blackwell, 2011). For the majority of human pathogenic fungi, impairment of host immune defenses is often a prerequisite for

Table 1 Epidemiology of blastomycosis in United States and Canada

invasive infection. However, the thermally dimorphic fungi can infect and cause disease in mammalian hosts with either intact or impaired immune defenses (Gauthier, 2015). Shared virulence traits include yeast growth 37°C (i.e., thermotolerance), intra-cellular survival, and upregulation of yeast-phase specific virulence factors that subvert host defenses (Gauthier, 2015).

The defining biologic feature of the thermally dimorphic fungi is the temperature-dependent reversible switch between hyphae and yeast which is known as the phase transition. Temperature is the predominant stimulus that drives the morphologic switch. Hyphal growth occurs at 22–25°C, whereas yeast growth occurs at 37°C. In addition to temperature, the uptake of exogenous cysteine is needed to complete the conversion to yeast following a increase in temperature from 22 to 25 to 37°C (Medoff *et al.*, 1987; Maresca *et al.*, 1981). Cysteine uptake induces resumption of mitochondrial respiration during the phase transition (Medoff *et al.*, 1987; Maresca *et al.*, 1981). In contrast to *Coccidioides* and *Paracoccidioides*, exogenous CO₂ tension or estradiol do not influence the morphologic switch of *Blastomyces* (Klotz *et al.*, 1984; Powell *et al.*, 1983; Shankar *et al.*, 2011). In vitro experiments

have demonstrated that engulfment of conidia by macrophages also accelerates the transition to yeast (Sterkel *et al.*, 2015). In vivo during infection, *Blastomyces* yeast undergo intracellular and extracellular replication, which is a conserved feature among the thermally dimorphic fungi (Sterkel *et al.*, 2015).

Molecular Regulation of the Phase Transition to Yeast

The discovery of a group III hybrid histidine kinase encoded by *DRK1* (Dimorphism Regulating Kinase-1) provided definitive proof that the phase transition to yeast was essential for virulence (Nemecek *et al.*, 2006; Lawry *et al.*, 2017). *DRK1* is part of high-osmolarity glycerol (HOG) signaling pathway which is important for adaptation to osmotic and oxidative stresses. Deletion of *DRK1* or reduction in *DRK1* transcript by RNA interference (RNAi) inhibits the conversion of conidia or hyphae to yeast at 37°C (Nemecek *et al.*, 2006). Although *DRK1*Δ cells remain viable at 37°C, they are locked as hyphae, exhibit alterations in the cell wall, fail to upregulate the essential yeast-phase virulence factor *BAD1* (*Blastomyces* adhesion-1, formerly WI-1), and are avirulent in a murine model of pulmonary infection (Nemecek *et al.*, 2006). At room temperature, *DRK1*Δ cells have reduced capacity to produce conidia (Nemecek *et al.*, 2006). The functional role of *DRK1* on the morphologic transition is conserved in *Histoplasma capsulatum* and *Talaromyces marneffeii* (formerly *Penicillium marneffeii*) (Nemecek *et al.*, 2006; Boyce *et al.*, 2011). *H. capsulatum* *DRK1* RNAi knockdown strains remain locked as hyphae at 37°C, fail to upregulate the essential virulence factor *CBP1* (Calcium-Binding Protein-1), and are avirulent in a murine model of pulmonary infection (Nemecek *et al.*, 2006). Deletion of *DRK1* impairs the germination of *T. marneffeii* conidia to yeast in macrophages (Boyce *et al.*, 2011).

Virulence Factors

In addition to thermotolerance, upregulation of yeast-phase virulence factors is critical for survival within the host. *B. dermatitidis* and *B. gilchristii* yeast upregulate *BAD1*, an essential virulence factor (Brandhorst *et al.*, 1999, 2003, 2013; Beaussart *et al.*, 2015; Finkel-Jimenez *et al.*, 2001, 2002). In vivo transcriptional profiling during a murine model of pulmonary infection demonstrated that *BAD1* was the most highly upregulated gene in the yeast transcriptome (Muñoz *et al.*, 2015). *BAD1* encodes a secreted multifunctional 120 kDa protein (Bad1) that can remain soluble in the extracellular milieu or bind back to coat yeast cells via its interactions with chitin in the cell wall (Brandhorst *et al.*, 1999, 2003, 2013; Beaussart *et al.*, 2015). Bad1 promotes adhesion of yeast cells to host tissues by binding heparin sulfate and adherence to host immune cells by binding with complement receptors (CR3, CD14) (Brandhorst *et al.*, 2013; Beaussart *et al.*, 2015; Finkel-Jimenez *et al.*, 2001). Soluble and bound Bad1 inhibit production of TNF-α by macrophages and neutrophils; however, the mechanisms are different. Bound Bad1 inhibits TNF-α production in a TGF-β-dependent manner whereas soluble Bad1 inhibits TNF-α production independent of TGF-β (Finkel-Jimenez *et al.*, 2001, 2002). In addition to affecting TNF-α, Bad1 impairs activation of CD4+ T lymphocytes, which in turn, reduces IL-17 and INF-γ (Brandhorst *et al.*, 2013). Deletion of *BAD1* renders *Blastomyces* avirulent in a murine model of pulmonary infection (Brandhorst *et al.*, 1999). Thus, *BAD1* is an essential virulence gene. In addition to Bad1 modulating the immune system, yeast cells also secrete dipeptidylpeptidase IVA (DppIVA), a serine protease that impairs the recruitment of innate immune cells to the lungs by inactivating granulocyte-macrophage colony stimulating factor (GM-CSF) (Sterkel *et al.*, 2016).

Other mechanisms that influence *Blastomyces* virulence include alteration in cell wall carbohydrate composition, relative resistance to oxidative and nitrosative killing, and zinc uptake. During the temperature-mediated shift from hyphae-to-yeast, the concentration of β-(1,3)-glucan in the cell wall decreases from 40% to <5% (Kanetsuna and Carbonell, 1971). This reduction has the potential to limit the ability of host immune cells to recognize *Blastomyces* yeast via dectin-1 and mannose receptors (Koneti *et al.*, 2008). From a clinical perspective, the paucity of yeast cell wall β-(1,3)-glucan renders the echinocandin antifungals ineffective for treatment and makes (1,3)-Beta-D-Glucan blood test unreliable for diagnosis (Nakai *et al.*, 2003; Girouard *et al.*, 2007). During infection, yeast cells upregulate superoxide dismutase and catalase, which may contribute to reduced sensitivity to reactive oxygen species (Muñoz *et al.*, 2015; Brummer *et al.*, 1992). In addition, yeast cells suppressed nitric oxide product by macrophages (Rocco *et al.*, 2011). The mechanism underlying resistance to nitric oxide killing has yet to be fully elucidated but is likely due to inhibition of inducible nitric oxide synthase enzymatic activity (Rocco *et al.*, 2011). During murine pulmonary infection, genes involved with zinc scavenging (*PRA1*) and uptake (*ZRT1*) are upregulated (Muñoz *et al.*, 2015). *PRA1* encodes a secreted zinc-binding protein that functions as a "zincophore", whereas *ZRT1* encodes a high-affinity zinc transporter (Muñoz *et al.*, 2015). Disruption of *PRA1* and *ZRT1* transcription by CRISPR/Cas9 gene editing results in attenuated virulence during pulmonary infection (Kujoth *et al.*, 2018).

In sharp contrast to histoplasmosis and coccidioidomycosis, disseminated infection with blastomycosis is common in patients with normal and impaired immune defenses (Hage *et al.*, 2015; Odio *et al.*, 2017). Recent data from the Marshfield Clinic in Wisconsin suggests that the propensity for dissemination is species specific (Meece *et al.*, 2010; Frost *et al.*, 2016). In patients infected with *B. dermatitidis*, disseminated infection occurred in 31.4%–33.6%, whereas 7.8%–9.3% with *B. gilchristii* had disseminated disease (Meece *et al.*, 2010; Frost *et al.*, 2016). Thus, *B. dermatitidis* is more likely to disseminate and *B. gilchristii* is more likely to remain localized to the lungs. Single nucleotide polymorphism (SNP) genotyping has identified significant allelic differences in 11 genes including those known to be involved with virulence (*BAD1*) and the temperature-dependent morphologic shift to yeast (*DRK1*) (Frost *et al.*, 2016). Subgroup analysis focusing on *B. dermatitidis* uncovered allelic differences for urease, septin1, and α-1,3-glucan synthase encoding genes (Frost *et al.*, 2016). Collectively, this suggests that

pathogen-related factors may influence dissemination. However, despite advances in understanding pathogenesis, the absence of a model system that mimics human disseminated disease has hindered the ability to delineate mechanism(s) that promote extrapulmonary spread. However, it is likely that multiple mechanisms influence dissemination including, but not limited to, subversion of host immune defenses, ability for intracellular replication in macrophages, suppression of nitric oxide production, and relative resistance to oxidative stress.

In vivo transcriptional profiling during murine infection has identified novel genes in *Blastomyces dermatitidis* that have the potential to influence dissemination (Muñoz *et al.*, 2015). This includes genes involved with nickel transport (*NIC1*), urease (*URE*), and cysteine metabolism (*CDG*, *SSU1*). Nickel is an important cofactor for the urease enzyme, which catalyzes the conversion of urea to ammonia and carbon dioxide. In *Coccidioides*, urease-encoding genes (*URE*) contributes to pathogenesis by enhancing tissue damage (Mirbod-Donovan *et al.*, 2006). In *Cryptococcus neoformans* *NIC1* and *URE1* promote extrapulmonary dissemination to the central nervous system (Singh *et al.*, 2013). In patients with disseminated blastomycosis, the most common extrapulmonary site of infection is the skin, occurring in 40%–80% (Chapman *et al.*, 2008). There is potential that upregulation of genes involved with cysteine catabolism could influence growth of *B. dermatitidis* in keratinized tissues such as skin. The dermatophyte *Arthroderma benhamiae* exports sulfite to degrade keratin to facilitate growth on keratinized tissues. In this process, cysteine dioxygenase (*CDG*) breaks down cysteine to sulfite which is then exported by a transmembrane sulfite efflux pump (*SSU1*) (Grumbt *et al.*, 2013). During in vivo infection, *B. dermatitidis* upregulates *CDG* and *SSU1* homologs (Muñoz *et al.*, 2015). Functional testing of these candidate genes (*NIC1*, *URE*, *CDG*, *SSU1*) in a model of disseminated infection is needed.

Molecular Regulation of the Phase Transition to Hyphae

Growth as hyphae is essential for genetic diversity via sexual reproduction, production of conidia, and survival in the environment. In *Blastomyces dermatitidis* and *Histoplasma capsulatum*, the conversion from yeast to hyphae following a drop in temperature from 37°C to 22–25°C is regulated in part by GATA transcription factor homologs *SREB* (Siderophore Biosynthesis Repressor in *Blastomyces*) and *SRE1* (Siderophore Repressor-1), respectively (Gauthier *et al.*, 2010; Marty *et al.*, 2015; Hwang *et al.*, 2012). Deletion of *B. dermatitidis* *SREB* or RNAi knockdown of *H. capsulatum* *SRE1* impairs the ability of yeast to convert to hyphae and results in excessive of siderophore biosynthesis and iron uptake (Gauthier *et al.*, 2010; Marty *et al.*, 2015; Hwang *et al.*, 2012). Siderophores are iron-gathering molecules produced by fungi to scavenge extracellular iron. The defect in the phase transition to hyphae is independent of alterations in siderophore biosynthesis and iron uptake (Gauthier *et al.*, 2010; Marty *et al.*, 2015). Using a combination of gene expression microarray, chromatin immunoprecipitation with sequencing and quantitative PCR, and functional testing indicated the defect in the morphologic shift in *B. dermatitidis* *SREBΔ* was due to reduced biosynthesis of neutral lipids and lipid droplets (Marty *et al.*, 2015). The defect in hyphal development at 22°C was temporally associated with reduced transcription of neutral lipid biosynthetic genes, decreased production of triacylglycerol and ergosterol, and a paucity of lipid droplets (Marty *et al.*, 2015). Lipid droplets are intracellular organelles composed of a triacylglycerol and ergosterol core and surrounded by a single phospholipid layer. The morphologic and lipid droplet defects in *SREBΔ* were partially restored when the media was supplemented with exogenous saturated fatty acids (Marty *et al.*, 2015). Supplementation with unsaturated fatty acids did not correct developmental or lipid droplet defects (Marty *et al.*, 2015). Other mechanisms that promote hyphal development include sensing of N-acetylglucosamine (GlcNAc), a component of chitin (Gilmore *et al.*, 2013). Exogenous GlcNAc accelerates *B. dermatitidis* and *H. capsulatum* hyphal development following a shift from 37°C to room temperature. Reduced transcription of GlcNAc transporters *NGT1* and *NGT2* delays hyphal development at room temperature (Gilmore *et al.*, 2013).

Immunology & Vaccine Development

Blastomyces uses several strategies to suppress and evade the immune system, however the host can use innate and adaptive immune cells to defend itself. In a murine model, macrophages and neutrophils kill a large percentage of conidia inhaled into the lungs (Sugar *et al.*, 1995). In immune competent hosts, CD4⁺ T lymphocytes coordinate the adaptive immune response to control infection by enhancing the fungicidal activity of phagocytes against the yeast (Bradsher *et al.*, 1987; Wüthrich *et al.*, 2011). This process requires TNF-α, INF-γ and IL-17 cytokines (Bradsher *et al.*, 1987; Wüthrich *et al.*, 2011). Cell mediated immunity (CMI) after *Blastomyces* infection can last for at least 2 years (Klein *et al.*, 1990).

The importance of CMI is underscored by recent findings in human populations. Individuals of Hmong ancestry have higher rates of epidemic and endemic pulmonary blastomycosis and have been studied for a genetic predisposition to infection (Roy *et al.*, 2013; Merkhofer *et al.*, 2019). Whole genome sequencing analysis revealed single nucleotide polymorphisms in immune response genes that distinguish individuals of Hmong ancestry from those of European ancestry (Merkhofer *et al.*, 2019). The IL-6 locus in particular displayed multiple polymorphisms that differed between the two groups. Likewise, IL-6 responses to stimuli were found to be significantly lower in the Hmong than in European ancestry individuals (Merkhofer *et al.*, 2019). IL-6 is a cytokine with pleiotropic effects on immune cells, but plays a critical role in the development of Th17 cells. The development of anti-fungal Th17 memory cells was correspondingly reduced in Hmong individuals, as compared to individuals of European ancestry (Merkhofer *et al.*, 2019). Finally, a murine model of infection showed similar defects in the development of anti-fungal adaptive immunity and resistance in animals that lacked any IL-6 production (Merkhofer *et al.*, 2019).

Vaccines that induce cell-mediated immune defenses have the potential to prevent invasive fungal infections, including blastomycosis. When *BAD1* null yeast (*BAD1Δ*) are injected subcutaneously in mice, it induces sterilizing immunity, which results in complete protection against lethal pulmonary infection (Wüthrich *et al.*, 2000). Following subcutaneous injection, *BAD1Δ* yeast are transported by inflammatory (CCR2⁺) monocytes to lymph nodes for antigen transfer and presentation to resident dendritic cells (Ersland *et al.*, 2010). This induces naïve CD4⁺ T lymphocytes to differentiate into Th17 cells via dectin-2/FcRγ/Syk/Card9, dectin-3, and mannan receptor signaling pathways (Ersland *et al.*, 2010; Wang *et al.*, 2014, 2015, 2016). In response to infection, differentiated Th17 cells migrate to the lungs and secrete IL-17, which in turn, recruits and activates neutrophils and macrophages (Wüthrich *et al.*, 2011). In the absence of CD4⁺ T cells, *BAD1Δ* vaccinated mice activate IL-17 CD8⁺ T lymphocytes (Tc17 cells) via Myd88-Akt1-mTOR signaling to mediate vaccine immunity against *Blastomyces* pulmonary infection (Nanjappa *et al.*, 2014, 2015, 2017).

The antigenic component of the *BAD1Δ* vaccine that induces immunity is a 13-amino acid sequence in calnexin (Wüthrich *et al.*, 2015). This antigenic sequence is conserved among ascomycete fungi including *H. capsulatum*, *Coccidioides posadasii*, *Aspergillus fumigatus*, *Fonsecaea pedrosoi*, and *Pseudogymnoascus destructans* (Wüthrich *et al.*, 2015). This knowledge has led to a calnexin-based vaccine. The addition of *Blastomyces* endogluconase-2 (Bl-Eng2) as an adjuvant greatly enhances the immunogenicity of the calnexin vaccine and protects mice against pneumonia (Wang *et al.*, 2017). Bl-Eng2 not only harbors adjuvant activity, but also contains antigenic epitopes for T-helper cells that mediate strong protective immunity against lethal experimental infection (Dobson *et al.*, 2020).

Clinical Manifestations of Blastomycosis

Overview

Blastomyces infection is typically acquired through inhalation of infectious particles that are aerosolized following disruption of soil. Following inhalation, these particles convert to yeast to cause pneumonia. Once infection is established and host immune defenses are avoided, *Blastomyces* yeast can remain localized to the lung or disseminate to almost any organ. Cutaneous inoculation following trauma is a rare and unusual mechanism of acquisition (Gray and Baddour, 2002; Graham and Callaway, 1982; Gnann *et al.*, 1983; Harris *et al.*, 2011).

Blastomyces infects humans and animals; however, blastomycosis is not considered a zoonotic disease because *Blastomyces* is not transmitted between animal-to-humans. The most common animal infected by *Blastomyces* are dogs, which have a 10-fold higher incidence than humans (Anderson *et al.*, 2014). Although humans and their pets can be infected simultaneously or sequentially, this is due to common source of exposure, not zoonotic transmission (Anderson *et al.*, 2014; Sarosi *et al.*, 1979).

Blastomycosis is known as the “great pretender” because it can mimic bacterial pneumonia, viral pneumonia, pulmonary tuberculosis, lung cancer, laryngeal cancer, skin cancer, pyoderma gangrenosum, and sarcoidosis (Lemos *et al.*, 2002; Bradsher, 2014). Pulmonary blastomycosis is often initially misdiagnosed as a bacterial infection that results in initiation of antibiotics rather than antifungals. In one study, patients received a median of 2.5 courses of antibiotics before blastomycosis was diagnosed (Alpern *et al.*, 2016). Another challenge in recognizing blastomycosis is the long incubation period following environmental exposure, 3 weeks to 3 months (Klein *et al.*, 1986a,b; Klein *et al.*, 1987a,b). Thus, blastomycosis can manifest in any season including the winter.

Human Blastomycosis

Pulmonary Blastomycosis

Pneumonia is the most common clinical manifestation of blastomycosis and occurs in 69%–93% of patients. (Chapman *et al.*, 1997; Vasquez *et al.*, 1998; Hussein *et al.*, 2009; Crampton *et al.*, 2002; Kralt *et al.*, 2009; Lemos *et al.*, 2002; Light *et al.*, 2008; Baumgardner *et al.*, 2004; Azar *et al.*, 2015). Severity ranges from asymptomatic infection, acute pneumonia, acute respiratory distress syndrome (ARDS), to chronic pneumonia (Davies and Sarosi, 1997). There are no pathognomonic clinical or radiographic manifestations to reliably distinguish blastomycosis from other pulmonary diseases. Acute pulmonary blastomycosis often mimics community-acquired pneumonia (CAP) with symptoms of cough, chest pain, fever, chills, decreased appetite, and malaise (Baumgardner *et al.*, 1992; Chapman *et al.*, 1997; Vasquez *et al.*, 1998; Crampton *et al.*, 2002; Kralt *et al.*, 2009; Baumgardner *et al.*, 2004; Azar *et al.*, 2015). Typical radiographic pattern for acute blastomycosis includes lobar consolidation and is indistinguishable from CAP (Fig. 3(A); Fang *et al.*, 2007). Patients with ARDS have involvement of all 5 lobes of the lung and experience rapid decompensation in respiratory status that requires either mechanical ventilation or extracorporeal membrane oxygenation (ECMO). Risk factors for severe pulmonary blastomycosis are multilobar pneumonia, diabetes, and immunosuppression (Kralt *et al.*, 2009; Azar *et al.*, 2015; Schwartz *et al.*, 2016). In chronic pulmonary blastomycosis, patients have slowly progressive symptoms over a period of months that include fever, chills, night sweats, cough, hemoptysis, weight loss, and malaise. Chest radiography often demonstrates dense consolidation or cavity lesions. Other radiographic patterns associated with blastomycosis include masses that mimic lung cancer, nodules (Fig. 3(B)), and interstitial infiltrates (Fang *et al.*, 2007). A miliary chest radiographic pattern suggests a high burden of infection, which in turn, increases the risk for respiratory failure if antifungal therapy is not quickly started (Fang *et al.*, 2007). Uncommon chest imaging findings include pleural effusion, empyema, and hilar adenopathy (Fang *et al.*, 2007).

Fig. 3 Pulmonary manifestations of blastomycosis. (A) Pulmonary infiltrate in the right lung (arrow). (B) Pulmonary nodule in the left lung (arrow).

Fig. 4 Skin lesions of blastomycosis. (A) Ulcerative skin lesion. (B) Verrucous skin lesion.

Disseminated Blastomycosis

Extrapulmonary dissemination of blastomycosis is estimated to occur in 15%–48% of infected persons and can infection almost any organ. (Baumgardner *et al.*, 1992; Chapman *et al.*, 1997; Vasquez *et al.*, 1998; Hussein *et al.*, 2009; Crampton *et al.*, 2002; Carlos *et al.*, 2010; Kralt *et al.*, 2009; Light *et al.*, 2008; Azar *et al.*, 2015; Lemos *et al.*, 2000). Risk factors for disseminated disease include infection with *B. dermatitidis* (versus *B. gilchristii*) and prolonged duration of pulmonary symptoms (Crampton *et al.*, 2002; Frost *et al.*, 2016). In HIV seropositive patients with a CD4 + T-lymphocyte count <200 cells/mm³, there is an increased risk for dissemination to the central nervous system (CNS) (Pappas *et al.*, 1992). In contrast, solid organ transplant recipients do not have a predilection CNS blastomycosis and overall dissemination rates range from 33% to 50% (Gauthier *et al.*, 2007; Grim *et al.*, 2012).

The most common sites for disseminated infection are the skin, bone, and prostate. Cutaneous blastomycosis often presents as papule that slowly expands to form ulcerative or verrucous lesions (Fig. 4). Any cutaneous region can be involved including the scalp, face, trunk, arms, and legs. Skin lesions can range from small (<1 cm) to large lesions that cause extensive cutaneous damage and heal by scarring.

The second most common site of extrapulmonary infection is the bone, occurring in 15%–44% (Chapman *et al.*, 1997; Vasquez *et al.*, 1998; Hussein *et al.*, 2009; Kralt *et al.*, 2009; Light *et al.*, 2008; Azar *et al.*, 2015; Lemos *et al.*, 2000). Bone infection or osteomyelitis is characterized by pain and soft tissue swelling (Oppenheimer *et al.*, 2007). Most patients will have concomitant pneumonia; however, a subset will not have obvious pneumonia (Oppenheimer *et al.*, 2007). The most frequently sites of osteomyelitis are the vertebrae, long bones (i.e., humerus, femur, tibia), and ribs. Infection in the bone can extend into the soft tissues to cause abscesses, skin ulcers, sinus tracts that drain pus, and septic arthritis (Oppenheimer *et al.*, 2007; Jain *et al.*, 2014). Vertebral osteomyelitis, which typically presents with back pain, can be complicated infection of the intervertebral disks (diskitis), epidural abscesses that compress the spinal cord, paraspinal soft tissue abscesses, and collapse of vertebrae resulting in neurologic impairment (Gehweiler *et al.*, 1970; Saccente *et al.*, 1998). Analogous to pulmonary blastomycosis, there are no radiographic findings that can distinguish bone infection from *Blastomyces* to bacterial osteomyelitis, tumor, or tuberculosis (Gehweiler *et al.*, 1970).

The third most frequent site of dissemination is the genitourinary (GU) system, which occurs in <10% of patients (Vasquez *et al.*, 1998; Hussein *et al.*, 2009; Crampton *et al.*, 2002; Kralt *et al.*, 2009; Light *et al.*, 2008; Azar *et al.*, 2015; Lemos *et al.*, 2000). Most patients with GU dissemination have concomitant pulmonary or cutaneous blastomycosis (Inoshita *et al.*, 1983). GU blastomycosis results in infection of the prostate (i.e., prostatitis) or epididymis and testicles (epididymo-orchitis). Prostatitis causes painful urination (i.e., dysuria), increased frequency of urination at night (i.e., nocturia), suprapubic pain, decreased

strength in urine stream, and bladder outlet obstruction (Inoshita *et al.*, 1983; Seo *et al.*, 1997). Epididymo-orchitis results in pain and swelling of the scrotum and testicles (Seo *et al.*, 1997). One case of male-to-female transmission has been reported, which suggests that prostate secretions and semen are potentially infectious (Craig *et al.*, 1970). GU blastomycosis in women is rare and typically results in tubo-ovarian abscess with or without peritonitis (Barocas and Gauthier, 2014).

CNS blastomycosis occurs in $\leq 10\%$ of patients and causes meningitis, intracranial mass, or brain abscess; involvement of the spinal cord is rare (Lemos *et al.*, 2000; Bariola *et al.*, 2010; Gonyea, 1978). In patients with AIDS ($CD4^+$ T-lymphocytes $\leq 200/\text{mm}^3$), CNS dissemination can occur in up to 40% (Pappas *et al.*, 1992). Isolated CNS blastomycosis is uncommon, the majority of patients (77%–81%) will have blastomycosis involving other organs such as the lung, skin, or bone (Bariola *et al.*, 2010; Gonyea, 1978; Bush *et al.*, 2013; Friedman *et al.*, 2000). The clinical manifestations of CNS blastomycosis are slowly progressive (weeks to months) and include headache, focal neurologic deficits, changes in mental status, and seizures (Bariola *et al.*, 2010; Gonyea, 1978; Bush *et al.*, 2013; Friedman *et al.*, 2000). Cerebral spinal fluid analysis demonstrates an elevated white blood cell count with a neutrophilic or lymphocytic predominance, elevated protein, and low glucose (Bariola *et al.*, 2010; Gonyea, 1978). Diagnosis of CNS blastomycosis can be challenging because the sensitivity of CSF culture is $\leq 45\%$ (Bariola *et al.*, 2010; Gonyea, 1978).

Blastomycosis in Pregnancy

Blastomycosis in pregnancy is rare with only 24 cases reported in the medical literature (Baker *et al.*, 2017; Austin *et al.*, 2019). Patients typically present with either pneumonia (74%) or disseminated disease (48%) in the 2nd or 3rd trimesters (Baker *et al.*, 2017). On the basis of 2 case reports, there is potential for mother-to-child transmission; however, the majority of neonates delivered vaginally to infected mothers are healthy (Baker *et al.*, 2017; Maxson *et al.*, 1992; Watts *et al.*, 1983). The route for maternal-to-child transmission is unclear, but includes intrauterine transmission or aspiration of infected vaginal secretions during birth (Maxson *et al.*, 1992; Watts *et al.*, 1983). *Blastomyces* infection does not increase the risk for congenital malformations; however, treatment with azole antifungals early in pregnancy can result in spontaneous abortion or an Antley-Bixler-like syndrome (cardiac and bone malformations) (Pursley *et al.*, 1996; Cottreau and Barr, 2016).

Blastomycosis in Immunocompromised Persons

Blastomycosis can infect patients immunocompromised by solid organ transplantation, malignancy, high-dose steroids, AIDS, and tumor necrosis factor alpha (TNF- α) inhibitors. In contrast to histoplasmosis and coccidioidomycosis, blastomycosis has been rarely reported in patients with primary immunodeficiency disorders (Sideritis *et al.*, 2010; Spinner *et al.*, 2016; Lee and Lau, 2017).

The incidence of blastomycosis in recipients of solid organ transplants (SOT) in the endemic region is 0.13%–0.14% (Gauthier *et al.*, 2007; Grim *et al.*, 2012). SOT recipients at high risk for respiratory failure, ARDS, and death due to blastomycosis (Gauthier *et al.*, 2007; Grim *et al.*, 2012; Kauffman *et al.*, 2014). A subset can be co-infected with opportunistic pathogens such as cytomegalovirus or *Aspergillus*. Disseminated disease occurs in 33%–50%, which is similar to the general population (15%–44%) (Gauthier *et al.*, 2007; Grim *et al.*, 2012; Kauffman *et al.*, 2014).

Blastomycosis in patients with AIDS is uncommon, even in highly endemic areas such as Wisconsin. This may be related to preservation of $CD8^+$ T-lymphocytes which provides protective immunity against *B. dermatitidis* (Gulzar and Copeland, 2004; Nanjappa *et al.*, 2014). Most AIDS patients with blastomycosis have pulmonary disease with 53% having disseminated disease (≥ 3 sites of infection in 33%), and up to 40% can have CNS involvement (Pappas *et al.* (1992)).

Patients with autoimmune disorders such as rheumatoid arthritis or inflammatory bowel disease that are treated with tumor necrosis factor alpha (TNF- α) inhibitors are at increased risk for invasive fungal infections and tuberculosis (Smith and Kauffman, 2009). In a large case-control study, the 2 most common infections for persons treated with TNF- α inhibitors were *Mycobacterium tuberculosis* (60%) and *H. capsulatum* (60%) (Salt *et al.*, 2016). Other infections were less common including blastomycosis (4%) (Salt *et al.*, 2016). There is a paucity of data regarding clinical manifestations and rates of dissemination in persons with blastomycosis who have received TNF- α inhibitors (Smith and Kauffman, 2009; Salt *et al.*, 2016; Smith *et al.*, 2015; Alpern *et al.*, 2016).

Diagnosis of Blastomycosis

The most important “diagnostic test” is considering blastomycosis in the differential diagnosis (Table 3). Once blastomycosis is suspected, a combination of culture and non-culture-based diagnostics can be used for diagnosis (Saccante and Woods, 2010). Culture-based diagnostics involve collecting clinical specimens for fungal staining and culture. Non-culture based diagnostics involve serologic or antigen tests.

The most rapid method for diagnosis is staining of clinical specimens to look for broad-based budding yeast (8–20 μm) with a doubly refractile cell wall (Saccante and Woods, 2010). Staining of respiratory specimens, purulent drainage, or skin samples with calcofluor, 10% potassium hydroxide, or Papanicolaou highlights the fungal cell wall (Saccante and Woods, 2010). In contrast, Gram staining, which is used for bacteria, will not result in optimal visualization of the thermally dimorphic fungi. The sensitivity of stained respiratory samples ranges from 50% to 90% and results are usually available within several hours (Saccante and Woods, 2010). Biopsied tissue specimens can be stained with Gomori methenamine silver (GMS) or periodic acid-schiff (PAS)

Table 3 Clinical suspicion of blastomycosis for persons that reside in or visit the endemic region

Risk factors for exposure	Nearby construction of homes, buildings, or roads Home remodeling Landscaping Logging Canoeing or tubing on a river Fishing by riverbanks Beaver dam exploration Use of a community compost pile Work in a microbiology laboratory Concomitant diagnosis in a pet such as a dog or cat ^a
Suggestive clinical findings	Infections of the lung, skin, or bone that do not respond to antibiotic therapy Pneumonia with cutaneous lesions or osteomyelitis CNS disease in setting of pneumonia, skin lesions, or osteomyelitis Acute respiratory distress syndrome (ARDS) ^b

^aBlastomycosis is not considered a zoonotic infection. Infection in a pet suggests a common source of environmental exposure.

^bAlthough there are many causes of ARDS, blastomycosis should be considered as part of the differential diagnosis in any person with ARDS who lives in or has visited the endemic region for blastomycosis.

(Saccante and Woods, 2010). Standard histopathology stains such as hematoxylin and eosin (H&E) poorly visualize *Blastomyces* yeast (Saccante and Woods, 2010). Tissues infected with *Blastomyces* yeast typically demonstrate neutrophil infiltration and granulomas known as pyogranulomatous inflammation (Saccante and Woods, 2010). Histopathology results are usually available within 24–48 h. Morphologic identification of *Blastomyces* yeast on stained clinical specimens correlates with culture results (Patel et al., 2010). Because fungal stains are not routinely performed on clinical specimens, these tests should be specifically ordered by the requesting health care provider.

All clinical specimens obtained for staining should have a paired sample sent to the microbiology lab for fungal culture. *Blastomyces* does not grow well on bacteriologic media and requires specialized media such as brain-heart infusion (BHI), potato dextrose agar (PDA), or Sabouraud dextrose agar. Growth in culture ranges from 5 to 28 days (Saccante and Woods, 2010). Most clinical laboratories incubate fungal cultures at 25–30°C, which will result in growth as hyphae (Saccante and Woods, 2010). Unfortunately, *Blastomyces* hyphae are not distinctive and visually appear similar other fungi. Thus, confirmation by chemiluminescent DNA probe, PCR analysis, or conversion to yeast is required (Saccante and Woods, 2010). The sensitivity for culture typically ranges from 72% to 92% (Chapman et al., 1997; Vasquez et al., 1998; Carlos et al., 2010; Kralt et al., 2009; Azar et al., 2015; Martynowicz and Prakash, 2002). Fungal cultures are not routinely performed and must be specifically ordered by the requesting health care provider.

Non-culture based diagnostics can be used in conjunction with staining and culture. Serologic tests such as complement fixation (CF) and immunodiffusion (ID) suffer from poor sensitivity ($\leq 25\%$ for CF and $\leq 40\%$ for ID) and have been largely replaced by a quantitative antigen test that detects galactomannan shed from the *Blastomyces* yeast cell wall (Vasquez et al., 1998; Martynowicz and Prakash, 2002; Klein et al., 1986b, 1987b; Richer et al., 2014; Durkin et al., 2004; Bariola et al., 2011; Connolly et al., 2012; Frost and Novicki, 2015). The antigen test can be performed on urine, blood, bronchoalveolar fluid, and cerebrospinal fluid. The sensitivity of the urine *Blastomyces* antigen assay is 76.3%–92.9% (Bariola et al., 2011; Connolly et al., 2012; Frost and Novicki, 2015). Data regarding sensitivity of the *Blastomyces* antigen assay on bronchoalveolar and cerebrospinal fluid is limited (Bariola et al., 2011; Akture et al., 2013; Walkty et al., 2017). The underlying burden of *Blastomyces* infection influences the sensitivity of the antigen assay in which patients with a higher infectious burden are more likely to have a positive test (Bariola et al., 2011). Serial measurement of urine antigen levels can be used to monitor response to therapy with a decline in antigen levels indicating a positive response to treatment (Frost and Novicki, 2015).

Overlapping structural similarity in the galactofuranose side chains in galactomannan can result in false positive *Blastomyces* testing in patients infected with *H. capsulatum* (96%–100%), *Paracoccidioides* (100%), and *Talaromyces marneffei* (70%) (Durkin et al., 2004). The galactomannan cross-reaction lowers specificity of the *Blastomyces* antigen test to 76.9–79% (Durkin et al., 2004; Bariola et al., 2011). However, the clinical impact on a false positive test due to cross-reaction is limited because the treatment regimens for *Blastomyces*, *Histoplasma*, *Paracoccidioides*, and *Talaromyces* are similar. Moreover, there is no overlap in the geographic distribution with *Paracoccidioides* spp. (Southern Mexico, Central America, South America) or *T. marneffei* (southeast Asia and China). Rarely, the *Blastomyces* antigen test can cross-react with *Cryptococcus* (2.9%) or *Aspergillus* (1.1%) (Durkin et al., 2004). Recent data suggests that the Platelia™ *Aspergillus* galactomannan assay performed on bronchoalveolar samples can cross-react in patients with pulmonary blastomycosis (Van Der Veer et al., 2012).

The newest non-culture based diagnostic test, serum (1,3)-Beta-D-Glucan, cannot reliably be used for diagnosis because *Blastomyces* yeast contain very little β -(1,3)-glucan ($< 5\%$) (Kanetsuna and Carbonell, 1971; Girouard et al., 2007). In contrast, the cell walls of *Histoplasma* yeast and *Coccidioides* sporangia contain more β -(1,3)-glucan and the serum 1,3- β -glucan can be positive in patients with these infections (Girouard et al., 2007; Zangeneh et al., 2015).

Basic science discoveries at the bench are beginning to enter the clinical realm with regards to the development of novel diagnostic tests. In addition to being an essential virulence factor, Bad1, is a highly immunogenic protein and results in a detectable antibody response in patients infected with *Blastomyces* (Richer *et al.*, 2014). On the basis of this data, a new serologic assay that detects antibodies against Bad1p has been developed (Richer *et al.*, 2014). The Bad1 antibody assay has a sensitivity of 87% and specificity of 94%–99% (Richer *et al.*, 2014). When the Bad1 antibody and *Blastomyces* antigen tests are combined, the sensitivity improves to 97% (Richer *et al.*, 2014). Because *Blastomyces* is the only known fungus that has the *BAD1* gene in its genome, cross-reactions with other fungi have not been reported (Muñoz *et al.*, 2015; Richer *et al.*, 2014). PCR assays that amplify *BAD1* have been developed for testing of cultures, paraffin-embedded tissues, and soil (Sidamonidze *et al.*, 2012; Burgess *et al.*, 2006). PCR-based soil analysis has been used to investigate human and canine blastomycosis outbreaks (Pfister *et al.*, 2011; Burgess *et al.*, 2006).

Treatment of Blastomycosis

Antifungal therapy is recommended for all patients diagnosed with blastomycosis (Chapman *et al.*, 2008; Limper *et al.*, 2011; Miller *et al.*, 2019). Selection of antifungals is influenced by severity of blastomycosis, sites of dissemination, underlying immunocompromise, presence or absence of pregnancy, drug-drug interactions, underlying congestive heart failure, and potential for cardiac arrhythmias due to QT prolongation. Guidelines for the treatment of blastomycosis have been published by the Infectious Diseases Society of America (IDSA), American Thoracic Society (ATS), and American Society of Transplantation (Chapman *et al.*, 2008; Limper *et al.*, 2011; Miller *et al.*, 2019).

Antifungals with activity against *Blastomyces* include polyene and azole drug classes. The newest class of antifungals, the echinocandins, have poor activity against *Blastomyces* yeast and should not be used for treatment (Chapman *et al.*, 2008; Limper *et al.*, 2011; Miller *et al.*, 2019). Polyene antifungals include amphotericin B deoxycholate and amphotericin B lipid formulations such as liposomal amphotericin B, amphotericin B lipid complex, and amphotericin B colloidal dispersion. Polyene antifungals can only be administered intravenously (IV). Side effects include infusion reactions, renal dysfunction, hypokalemia, and hypomagnesemia. Lipid amphotericin B (AmB) formulations have reduced frequency of infusion reactions and renal dysfunction compared to amphotericin B deoxycholate. Salt loading by administering intravenous 0.9% normal saline before and after AmB infusions can reduce the rate of renal dysfunction. Similarly, IV or oral replacement of potassium and magnesium can be used to correct or minimize AmB-mediated renal wasting of these electrolytes. AmB deoxycholate results in cure in 97% when cumulative dosage is > 2 g (Chapman *et al.*, 2008). Lipid formulations are predicted to be equally efficacious as AmB deoxycholate but with lower rates of infusion reactions and renal dysfunction (Chapman *et al.*, 2008). Thus, lipid AmB formulations are preferred over AmB deoxycholate.

Azole antifungal options for treatment of blastomycosis include itraconazole, voriconazole, posaconazole, isavuconazonium sulfate, and fluconazole (Chapman *et al.*, 2008; Limper *et al.*, 2011; Miller *et al.*, 2019). Azoles can be administered by IV or oral routes with the exception of itraconazole, which can only be given oral (IV formulation was discontinued). Itraconazole is the preferred azole for treatment of blastomycosis because it has excellent activity against *Blastomyces* and results in a 95% cure rate for patients with non-CNS blastomycosis. However, caution is needed in patients with underlying congestive heart failure due to its negative inotropic effect on cardiac function (Ahmad *et al.*, 2001). In addition, itraconazole can induce hypokalemia. Fluconazole, voriconazole, and posaconazole can prolong the QT interval, which can precipitate cardiac arrhythmias, especially in conjunction with other QT-prolonging medications. In contrast, isavuconazonium sulfate shortens the QT interval and is contraindicated in patients with congenital short QT syndrome (Keirns *et al.*, 2017). Prior to initiation of azole antifungals, a comprehensive medication assessment is needed because azoles have numerous drug interactions. In all patients who have the potential for pregnancy, a pregnancy test is needed before azole initiation because azoles can induce spontaneous abortion and have teratogenic effects on the developing fetus, especially in the first trimester (Pursley *et al.*, 1996; Cottreau and Barr, 2016). Thus, pregnant patients with blastomycosis should be treated with AmB.

Immunocompetent patients with severe pulmonary or severe disseminated blastomycosis require hospitalization and induction therapy with a lipid formulation of amphotericin B (Lipid AmB) for 1–2 weeks. This is followed by step-down therapy with itraconazole for 6–12 months (Table 4; Chapman *et al.*, 2008; Limper *et al.*, 2011). For patients with blastomycosis that has disseminated to the CNS, the duration of lipid AmB therapy is 4–6 weeks before starting step-down therapy with voriconazole, fluconazole, or itraconazole (Table 4). Voriconazole has become the preferred agent for step-down therapy in patients with CNS blastomycosis because of its excellent CNS penetration and activity against *Blastomyces* (Chapman *et al.*, 2008; Limper *et al.*, 2011; Miller *et al.*, 2019). Although fluconazole also has excellent CNS penetration, it is not as potent against *Blastomyces* as other azoles (Chapman *et al.*, 2008; Miller *et al.*, 2019). Despite limited penetration of the blood brain barrier, itraconazole can be used to treat CNS blastomycosis (Bush *et al.*, 2013). In addition, there are reports indicating success of posaconazole for treatment CNS blastomycosis (Miller *et al.*, 2019). For patients with disseminated blastomycosis involving the bone, treatment duration is 12 months (Table 4) (Chapman *et al.*, 2008; Limper *et al.*, 2011).

Immunocompetent patients with mild-to-moderate pulmonary or disseminated blastomycosis, azole antifungal therapy can be initiated in the outpatient setting and continued for 6–12 months (Table 4; Chapman *et al.*, 2008; Limper *et al.*, 2011). When Itraconazole, voriconazole, posaconazole, or isavuconazonium sulfate are started, loading dosing is recommended before starting maintenance dosing. To optimize serum drug levels for itraconazole capsules, it should be administered with food and an acidic beverage. Itraconazole capsule formulation should not be used in patients taking proton pump inhibitors or histamine-2 blockers

Table 4 Treatment of blastomycosis

Site of infection	Severity	Patient population	Recommended therapy
CNS	Any severity	Non-immunocompromised or immunocompromised	Lipid AmB 5 mg/kg IV daily for 4–6 weeks → Step-down therapy with voriconazole, fluconazole, or itraconazole for at least 12 months of total therapy ^a
Pulmonary	Severe	Non-immunocompromised or immunocompromised	Lipid AmB 3–5 mg/kg IV daily for 1–2 weeks → itraconazole for 6–12 months (12 months for immunocompromised patients) ^a . For patients with ARDS can consider concurrent corticosteroids (40–60 mg prednisone for 1–2 weeks) as well as combination antifungal therapy (lipid AmB plus azole)
Disseminated	Mild-moderate	Non-immunocompromised	Itraconazole for 6 months
	Mild-moderate	Immunocompromised	Lipid AmB 3–5 mg/kg IV daily for 1–2 weeks → itraconazole for 12 months ^b
	Severe	Non-immunocompromised or immunocompromised	Lipid AmB 3–5 mg/kg IV daily for 1–2 weeks → itraconazole for 12 months ^a
	Mild-moderate	Non-immunocompromised	Itraconazole for 6–12 months (≥ 12 months for osteomyelitis)
Any site	Mild-moderate	Immunocompromised	Lipid AmB 3–5 mg/kg IV daily for 1–2 weeks → itraconazole for 12 months (≥ 12 months for osteomyelitis)
	Any Severity	Pregnancy	Lipid AmB 3–5 mg/kg IV daily

^aCan consider combination therapy with Lipid Amphotericin B and azole antifungal.

^bAlthough not well-studied, ATS and AST guidelines suggest itraconazole can be used as initial therapy for select immunosuppressed patients with mild-to-moderate blastomycosis; however, azole antifungals are fungistatic against *Blastomyces* spp., whereas AmB is fungicidal.

Source: Severe infection requires hospitalization. For Mild-to-moderate infection, therapy can be initiated in the outpatient setting. Immunocompromise includes but is not limited to HIV/AIDS, high-dose steroids, TNF-alpha inhibitors, solid organ transplantation, solid and hematologic malignancy. Azole dosing in adults: Itraconazole 200 mg orally TID × 3 days → 200 mg po BID or QD with dosing based on serum itraconazole levels, Voriconazole 6 mg/kg IV or PO BID × 1 day → 4–6 mg/kg (check dosing) IV or PO BID with dosing based on serum voriconazole trough levels, Fluconazole 800 mg IV or PO daily. Azole dosing in children: itraconazole 10 mg/kg per day with maximum of 400 mg daily; voriconazole dosing in children 2–12 years old is 9 mg/kg/dose IV or orally every 12 h for 2 doses, then 8 mg/kg/dose IV every 12 h or 9 mg/kg/dose orally every 12 h (maximum dose 350 mg/dose). Amphotericin B dosing in adults and children: Lipid Amphotericin B 3–5 mg/kg IV daily; Amphotericin B deoxycholate 0.7–1.0 mg/kg IV daily.

because they reduce gastric acidity, which in turn, decreases absorption leading to subtherapeutic drug levels. In contrast, itraconazole solution does not require gastric acidity for absorption and should be administered without food or an acidic beverage. Voriconazole should be taken without food, whereas posaconazole delayed release capsules and isavuconazonium sulfate can be administered irrespective of food. Therapeutic drug monitoring (TDM) is recommended when itraconazole, voriconazole, or posaconazole are used for treatment. TDM can be considered for isavuconazonium sulfate. TDM involves measuring serum levels of antifungal drugs to assess if the concentration in a therapeutic range (e.g., 1–5 µg/mL).

Immunosuppressed patients with pulmonary or disseminated blastomycosis should receive 1–2 weeks of AmB followed by 1 year of azole antifungal therapy (Table 4; Chapman *et al.*, 2008; Limper *et al.*, 2011). Similar to immunocompetent patients, lipid AmB is preferred over AmB deoxycholate (Chapman *et al.*, 2008; Limper *et al.*, 2011; Miller *et al.*, 2019). The IDSA & AST guidelines indicate that some patients with irreversible immunosuppression may require life-long antifungal therapy; however, except for patients with AIDS with persistent CD4 + T-lymphocytopenia (≤ 150 –200/µL), there are no specific criteria regarding which patients require indefinite therapy. For solid organ transplant recipients, the risk of relapse is low when treated for 12 months (Gauthier *et al.*, 2007; Grim *et al.*, 2012).

In patients with intracranial abscesses and osteomyelitis including spinal osteomyelitis complicated by vertebral collapse or neurologic impingement, surgical intervention should be considered in conjunction with antifungal therapy. Adjunctive steroids for 1–2 weeks (e.g., prednisone 40–60 mg or equivalent) can be considered in addition to AmB in patients with ARDS (Chapman *et al.*, 2008; Limper *et al.*, 2011; Miller *et al.*, 2019; Table 4). Several case reports have suggested a survival benefit; however, a large retrospective study was unable to provide definitive conclusions regarding the benefit of adjuvant steroids (Lahm *et al.*, 2008; Plamondon *et al.*, 2010; Schwartz *et al.*, 2016). Although not well studied, combination therapy with AmB plus an azole can be considered in patients with severe pulmonary blastomycosis or CNS involvement (Table 4; Limper *et al.*, 2011).

Outcomes and Mortality

When blastomycosis is recognized early and prompt therapy is initiated, clinical outcomes are excellent. However, in patients with ARDS due to blastomycosis, mortality ranges from 40% to 89% (Vasquez *et al.*, 1998; Azar *et al.*, 2015; Schwartz *et al.*, 2016; Lemos *et al.*, 2001; Meyer *et al.*, 1993). In SOT recipients with ARDS, mortality is 67% (Gauthier *et al.*, 2007). From 1990–2010, the age-adjusted mortality rate for blastomycosis was 0.21 / 1,000,000 person-years resulting in 19,097 years of life lost (Khuu *et al.*, 2014). Highest mortality rates occurred in persons ≥ 65 -years-old and in Native Americans (Khuu *et al.*, 2014). As expected the majority of deaths occurred within the endemic region, particularly the midwest and southern United States (Khuu *et al.*, 2014). Early recognition of blastomycosis along with initiation of effective therapy is currently the best approach to reduce mortality. There are no practical methods that can be introduced in a wide-spread manner to reduce environment-to-human transmission. The live-attenuated *Blastomyces* vaccine (BAD1Δ strain) is not commercially available and has not been tested in humans.

Introduction

Paracoccidioidomycosis (PCM) is the prevalent systemic mycosis in Latin America, with 80% of cases being registered in Brazil, followed by Colombia, Venezuela and Argentina (Brummer *et al.*, 1993; Martinez, 2015). In Brazil, most cases are concentrated in the southeast region (States of São Paulo, Rio de Janeiro, Minas Gerais and Espírito Santo), west and middle-west (Mato Grosso do Sul and Goiás) and South (Paraná, Santa Catarina and Rio Grande do South). However, other regions have reported cases, especially the amazonian States of Pará, Tocantins, Maranhão and Rondônia (Martinez, 2015). Paracoccidioidomycosis has also been reported in Europe, the USA, Africa and Asia, but all cases are imported since the affected individuals were visitors or had worked in endemic areas in Latin America (Martinez, 2015). The fungal agent *Paracoccidioides* spp. preferably inhabits in a moist environment, with average annual temperature of 18–24°C and rainfall range of 900–1800 mm (Restrepo, 1985).

The disease was described by Adolfo Lutz, a Brazilian physician, in 1908 after examining oral lesions in two patients from São Paulo City (reviewed by Taborda *et al.*, 2016; Moreira, 2008) and originally designated as pseudococcidial hyphoblastomycosis to differentiate from coccidioidomycosis and hyphoblastomycosis (Lacaz *et al.*, 1991). Splendore in 1912, suggested the classification of the agent in the genus *Zymonema*, thus creating the name *Zymonema brasiliense*. The disease was designated as Brazilian blastomycosis, but, since it had been reported in different countries in South America, the disease was assigned as South American blastomycosis or Lutz and Splendore-Almeida disease (Lacaz, 1982). The term Paracoccidioidomycosis was established in 1971 in Medellín, Colombia, during a meeting of the American Continent Mycologists, widely accepted since then (Lacaz, 1982). After systematic studies, in 1930, Floriano Paulo de Almeida officially named the fungal agent as *Paracoccidioides brasiliensis* (Almeida, 1930) and classified by Ajello (Ajello, 1977) as in Kingdom Fungi, Phylum Eumycota, Subdivision Deuteromycotina, class Hyphomycetes, Order Moniales, Moniliaceae Family, Genus and Species *Paracoccidioides brasiliensis*. Based on phylogenetic studies using molecular tools *P. brasiliensis* was positioned along with other dimorphic fungi (*Coccidioides posadasii*, *Coccidioides immitis*, *Blastomyces dermatitidis* and *Histoplasma capsulatum*) in the Kingdom Fungi, Phylum Ascomycota, Plectomycetes class, Order Onygenales, Onygenaceae Family, Genus and Species *Ajellomyces brasiliensis*, then again called *Paracoccidioides brasiliensis* (San-Blas *et al.*, 2002; Arantes *et al.*, 2015).

Paracoccidioidomycosis is a chronic granulomatous systemic mycosis, caused by a fungus of genus *Paracoccidioides*. One of the main characteristics of this genus is the thermal dimorphism, mycelial form at 25°C characterized as saprophytic and yeast as the pathogenic form at 35–37°C (reviewed by Taborda *et al.*, 2018)). The habitat of *Paracoccidioides* spp. has not yet been determined precisely. Soil samples from different locations in Venezuela, Argentina and Brazil (reviewed by Franco *et al.*, 2000)) support the hypothesis that the soil is the natural habitat of the fungus. In addition, isolations of *P. brasiliensis* from wild animals such as armadillos (Bagagli *et al.*, 1998), bats (Grose and Tamsitt, 1965) and even dog food (Ferreira *et al.*, 1990) have been reported. Also, genomic analysis of samples from animals living in the soil of endemic areas, such as guinea pig (*Cavia aperea*), raccoon (*Procyon cancrivorus*) and armadillo (*Dasypus septemcinctus*), further indicates acquisition of the infection from the soil in these areas. (Richini-Pereira *et al.*, 2008).

It is important to stress that except for humans, the most frequent host among mammals is the armadillo ((mainly *Dasypus novemcinctus*) but the fungus can occur in other species). *Paracoccidioides* spp. has been isolated ca. 75%–100% from armadillo captured in hyper-endemic areas of PCM, showing a high frequency of infection (Corredor *et al.*, 1999; Hrycyk *et al.*, 2018). The armadillos seem to favor the infection by *Paracoccidioides* spp. yeasts, such as the body temperature (between 32.7 and 35°C), low cellular immunity and constant contact with the soil (Bagagli *et al.*, 2008). It is hypothesized that parasitism in these animals would make it possible to preserve the saprophyte form and contribute to sexual reproduction, by promoting the proximity of mating types in a protected environment, such as the armadillo tissue or organs (Bagagli *et al.*, 2006).

For more than 100 years, only one species was recognized in the Genus: *Paracoccidioides brasiliensis*. Phylogenetic studies have classified *P. brasiliensis* into four cryptic species (S1, PS2, PS3 and PS4) with different evolutionary characteristics and geographic distribution. S1 is considered a recombinant monophyletic group with a wide distribution in South America, being responsible for most cases of PCM. PS2 is also recombinant but paraphyletic, found in Brazil and Venezuela. PS3 is a clonal and monophyletic population, registered only in Colombia. The PS4 group is classified as monophyletic with clinical isolates from Venezuela (Matute *et al.*, 2006; Theodoro *et al.*, 2012). In parallel, a second species was proposed based on phylogenetic and comparative genomic data, recombination analysis, and morphological characteristics and designated as *P. lutzii* (formally known as Pb01-like) (Desjardins *et al.*, 2011; Teixeira *et al.*, 2014). It was estimated that *P. lutzii* monophyletic group was separated from groups S1, PS2 and PS3 approximately 30 million years ago (Teixeira *et al.*, 2014). This species is endemic in the North and Midwest regions of Brazil (mainly in States of Rondônia, Mato Grosso and Goiás) and shares some geographical areas with the S1 group (Bocca *et al.*, 2013; Teixeira *et al.*, 2014). Turissini *et al.* (2017) expanded the phylogenetic studies and showed that despite low levels of genetic difference among the four cryptic species of the *P. brasiliensis*, they are indeed well separated species indicating that cryptic species (S1, PS2, PS3 and

PS4) should be elevated to taxonomical species status (Turissini *et al.*, 2017). The authors propose therefore to adopt the names *P. lutzii*, *P. brasiliensis* (S1), *P. americana* (PS2), *P. restrepiensis* (PS3) and *P. venezuelensis* (PS4) (Turissini *et al.*, 2017).

Morphological Aspects

Paracoccidioides spp., are considered dimorphic fungi depending on temperature to change their shape. The fungal species develop as mold at room temperature (19–25°C) and are then known as the saprophytic phase. Otherwise, at temperatures ranging 35–37°C, fungi become unicellular yeasts (Fig. 1), consisting in the parasitic phase (reviewed in Taborda *et al.*, 2018).

Depending on the culture medium, nutrients and temperature, colonies assume different characteristics. At room temperature, white fungal colonies grow slowly well adherent to the medium (Fig. 2(A)). When examined under the microscope, and using specific culture media, fine, septated mycelial filaments with conidia, arthroconidia, aleurioconidia and arthroconidia are seen (Conant and Howell, 1942; Neves and Bogliolo, 1951; Pollak, 1971). Conidia are small, less than 5 µm, with different shapes and sites on the parental mycelium (Bustamante-Simon *et al.*, 1985). The conidia-to-yeast transition occurs in 96 h at 37°C and colonies now show transition to cream colonies known as cerebriform and yeast-like which appear after 10–20 days (Brummer *et al.*, 1993; Fig. 2(B)). The yeast cells are similar to those detected in patients. Spherical cells (3–30 µm but some cells

Fig. 1 Micrograph of typical “pilot wheel” yeast cells of *P. brasiliensis* seen on direct examination of culture (120x).

Fig. 2 Macroscopic colonies: (A) of mycelium (room temperature) and (B) yeasts (37°C) in BHI Agar.

may reach 60 µm) with thin and thick walls are seen; along the cell surface single or multiples narrow-necked buds (2–10 µm) (Brummer *et al.*, 1993).

Epidemiological Aspects

The infection is acquired when propagules from the mycelial phase of the fungus are inhaled and, through the respiratory tract, install primarily in the pulmonary alveoli. The transition to the yeast phase starts in the lung and cell transformation is essential for the infection to establish the disease that can spread via hematogenous and/or lymphatic routes to any part of the organism (reviewed by Souza and Taborda, 2020). PCM is mostly manifested in male individuals, between 30 and 60 years of age, mostly rural workers in endemic areas. People from urban regions may also have contact with the fungus when visiting endemic areas. Other conditions such as smoking and excessive alcohol consumption are considered risk factors for the establishment of the disease (Shikanai-Yasuda *et al.*, 2017; Souza and Taborda, 2020). The hormone 17- β -estradiol is related to the fungal dimorphism and may protect women against the disease. Studies show that this hormone inhibits the transition from mycelium to yeast in a dose-dependent manner (Aristizábal *et al.*, 2002). It is believed that the Estradiol Binding Protein – PLE – present in the fungal cytoplasm binds to the 17- β -estradiol and blocks the conversion from the infective phase to the pathogenic phase (Shankar *et al.*, 2011). In addition to the hormones, PCM has already been reported in patients undergoing cytotoxic treatment or immunosuppressive therapy against cancer (Marques, Lastória and Marques, 2011), transplant patients (Shikanai-Yasuda *et al.*, 1995) and rheumatoid arthritis (Woyciechowsky *et al.*, 2011). It is assumed that cytotoxic drugs can reactivate a latent lesion, causing an acute lung infection, probably due to the impairment of the immune system due to chemotherapy and radiotherapy.

PCM is the most important systemic mycosis in Latin America and the countries with the highest number of cases are Brazil, Colombia, Venezuela and Argentina. Brazil has 80% of the total cases, and the southeast, south and midwest regions are the most prevalent (Martinez, 2017; Souza and Taborda, 2020). PCM is the eighth cause of mortality from chronic infectious diseases, reaching rates of 1.65 deaths per million inhabitants (Bocca *et al.*, 2013). In the period from 1996 to 2006 there were 517,058 deaths from infectious and parasitic diseases in Brazil. Systemic mycoses were responsible for 3583 deaths, with paracoccidioidomycosis being cited in approximately 51.2% deaths recorded in this period, occupying the tenth position, in this survey, among infectious and parasitic diseases with high mortality (Prado *et al.*, 2009). In 2010, it was estimated that 3360 new cases of PCM per year occur in Brazil alone (Martinez, 2010).

There are two progressive clinical forms of the disease: acute or subacute (juvenile type), which involves 3%–5% of cases, is characterized by having a severe faster course (weeks or months), with involvement of the reticuloendothelial system (spleen, liver, lymph nodes and spinal cord) rather than pulmonary involvement. Active replicating fungi and poor granuloma formation are found in the tissues. The chronic form (adult type) occurs in more than 90% of cases, as the disease takes months or years to establish, being, in most cases, asymptomatic. Pulmonary manifestations are the best indicators of this form of the disease, which can also spread to other organs and/or systems. Patients with the acute form of mycosis have high levels of antibodies depending on the mycosis severity. The reason for this clinical dichotomy is not clear and it is assumed that specific characteristics of the parasite-host relationship contribute to it (Benard, 2008; Benard *et al.*, 2012b; Vidal *et al.*, 2014).

Laboratorial Diagnosis

The laboratory diagnosis is relevant since some clinical aspects are shared with other fungal diseases such as: cryptococcosis, histoplasmosis, chromoblastomycosis, coccidioidomycosis and other diseases including tuberculosis, toxoplasmosis, leishmaniasis, cysticercosis, infectious mononucleosis, leprosy, sarcoidosis, syphilis, lymphoma, leukemia, neoplasms, pneumoconiosis, interstitial pneumonitis and Crohn's disease (Shikanai-Yasuda *et al.*, 2017).

The gold standard diagnosis of PCM is based on visualization of yeast cells in biological specimens and isolation of the fungus in culture (Moreira, 2008; Souza and Taborda, 2020). For isolation of the fungus it is recommended the use of Sabouraud dextrose agar or brain heart infusion agar (BHI) containing chloramphenicol and cycloheximide. The clinical specimens (sputum, bronchoalveolar lavage, scraped injury, ganglion aspirate, biopsy fragment) in culture medium are kept 15–30 days at 25–30°C. In the mycelial form, the fungus grows as white, cottony or glabrous colonies and there are no structures that can be associated to *Paracoccidioides* spp. Reversion to yeast form is achieved by changing the temperature to 36–37°C for at least 15 days resulting in cerebriform colonies. In this phase, it is possible to visualize yeast with multiple peripheral buds characteristic of the fungus (Shikanai-Yasuda *et al.*, 2017; Souza and Taborda, 2020). The clinical specimens treated with 10%–20% of potassium hydroxide (KOH) can be used for yeast cell visualization under an optical microscope (Fig. 3). Usually, oval, elliptical cells with 3 µm to 30 µm in diameter with refringent double contour wall and multiple peripheral buds in the typical “pilot wheel” (Shikanai-Yasuda *et al.*, 2017; Souza and Taborda, 2020) are of diagnostic value. Another important alternative as a diagnostic tool is the lesion biopsy. Special stains such as Gomori-Grocott or Schiff's periodic acid can assist in the diagnosis by detecting granulomas and the presence of typical yeast with multiple peripheral buds (Fig. 4; Taborda *et al.*, 2018).

Other important tools for diagnosis and follow-up of patients are the serological tests. Specific antibodies to *Paracoccidioides* spp. correlate to the severity of the clinical form, being high in the acute/subacute form and in the disseminated form (Vidal *et al.*, 2014). Although different techniques have been described in the last years, immunoprecipitation methods

Fig. 3 Smear of a patient's superficial lesion on a KOH mount showing (black arrow) a multi-budding yeast cell, pathognomonic of *Paracoccidioides* spp. Two isolated yeast cells (red arrows) are also seen, which do not permit the specific diagnosis of PCM.

Fig. 4 Lung from infected mice with *P. brasiliensis* and stained by Gomori-Grocott. Multiple budding yeast cells characteristic of genus *Paracoccidioides*.

as in the counterimmunoelectrophoresis and double immunodiffusion still show excellent sensibility and specificity with 80%–95% diagnostic potential (Vidal *et al.*, 2014; Shikanai-Yasuda *et al.*, 2017). Other assays as enzyme linked immunosorbent assay (ELISA) or immunoblot/dot-blot techniques can also be used (de Camargo, 2008; Kamikawa *et al.*, 2017).

The immunoprecipitation methods are widely used in Latin America; however, the lack of standardization of methods and production of antigens sometimes present in the tests used may lead to controversial results (Vidal *et al.*, 2014). False negative results may be obtained in patients with localized lesions or with immunosuppression as in AIDS (Shikanai-Yasuda *et al.*, 2017). False positive results may occur in patients with other fungal infections such as histoplasmosis and aspergillosis or with leishmaniasis (de Camargo, 2008; Shikanai-Yasuda *et al.*, 2017). The main diagnostic antigen of *P. brasiliensis* is the 43 kDa glycoprotein (Puccia *et al.*, 1986) largely used in serological tests (Travassos *et al.*, 2004). The sensibility and specificity of gp43 for

P. brasiliensis and other cryptical isolates is excellent, but not for *P. lutzii* (Shikanai-Yasuda *et al.*, 2017). Although there is no consensus in the serology for *P. lutzii*, Gegembauer *et al.* (2014) developed a serological test with a specific antigen.

Additional diagnostic resources have been developed, such as polymerase chain reaction (PCR) tests, widely used in the diagnosis of infectious diseases. Specifically, in PCM, several authors have described variations in the methods with good results (Bialek *et al.*, 2000; Gomes *et al.*, 2000; Motoyama *et al.*, 2000; Rocha-Silva *et al.*, 2018) however, PCR in the laboratory routine still needs more experimentation. MALDI-TOX MS (matrix-assisted laser desorption ionization-time of flight mass spectrometry) has been used for differentiation of isolates of *P. brasiliensis* and *P. lutzii*, previously characterized by molecular techniques, and all isolates were correctly identified (de Almeida *et al.*, 2015).

Pathogenesis and Histopathology

The influence of genetic traits on the mycosis has yet to be elucidated. The observation that only a very small proportion (estimated as less than 2%) of the individuals in endemic areas exposed to the fungus develops the mycosis (Martinez, 2017), points to idea that the host's immunogenetic background plays a role in the susceptibility/resistance to PCM-disease. The occurrence, although rare, of PCM in individuals with inborn errors of the immune system such as defects of the IL-12/IL-23-IFN- γ axis also gives support to this possibility (de Moraes-Vasconcelos *et al.*, 2005; Schimke *et al.*, 2017). PCM has been associated with polymorphisms in some (e.g., IL12RB1, IL4, IL10) but not other (CTLA4, TNF and IFNG) genes related to the immune response (Bozzi *et al.*, 2006; Lozano *et al.*, 2011; Mendonça *et al.*, 2015; Carvalho *et al.*, 2016). The same holds to some class I and class II HLA alleles (Montoya de Restrepo *et al.*, 1983; Lacerda *et al.*, 1988; Goldani *et al.*, 1991). Probably the patient's clinical presentation also bears some relation with his genetic background. A small study suggested that in patients with the unifocal chronic form of the disease (a mild clinical presentation in which lesions are restricted or localized), the HLA allele that was most commonly seen was DRB1*11 (Sadahiro *et al.*, 2007). Clearly, large-scale genetic studies in human PCM are still required to elucidate these aspects.

The role of the host's genetic background in susceptibility to PCM has been more clearly demonstrated in mice models of the mycosis, where resistance and susceptibility varied according to the mouse strain (Singer-Vermfs *et al.*, 2008). Differences not only in adaptive immune response patterns but also in innate immunity (e.g., magnitude of neutrophils influx into the lungs) and type of extracellular matrix composition of the granulomatous lesions were described in these models (Xidieh *et al.*, 1999; Pina, 2006; Sperandio *et al.*, 2015).

However, the difficulty in understanding many of the susceptibility/resistance aspects is largely due to the fact that the events that take place at the initial stages of the infective process are unknown, since patients are diagnosed months to years after the initial exposure to the fungus (Benard, 2008). Data from case-reports, small series of cases, and autopsies studies indicate that the primary PCM lesions occur in the lungs after inhalation of fungal propagules (Brass, 1969; Angulo-Ortega, 1972; Giraldo *et al.*, 1976; Franco *et al.*, 1987; Londero *et al.*, 1996). This has been also suggested in experimental models of PCM established through intra-nasal instillation of *P. brasiliensis* conidia (Mcewen *et al.*, 1987). As in other systemic mycoses, the infection initiates when conidia reach the terminal bronchi or alveolar spaces and transform into yeast cells. Most frequently, the local immune response controls this initial inoculum, either fully eradicating the fungus or leaving a few quiescent foci with dormant yeast cells located in the lungs and mediastinal lymph nodes. This has been illustrated by the observation in asymptomatic individuals the presence of residual or regressive pulmonary lesions (called paracoccidioidomas), witnessing the formation of a primary pulmonary complex much similar to that described in the pathogenesis of pulmonary tuberculosis (primary complex of Ghon) (Angulo-Ortega, 1972; Giraldo *et al.*, 1976; Severo *et al.*, 1979; Melo and Londero, 1983; Londero *et al.*, 1996; Santos *et al.*, 1997). Eventually, a few yeast cells may escape this initial local response and disseminate through the lymphohematogeneous route, giving rise to subclinical and quiescent foci in other organs and systems (Angulo-Ortega, 1972; Benard *et al.*, 2013). In most cases this prior initial pulmonary infection tends to pass unnoticed.

Rarely, for yet unknown reasons, the immune response fails to control the initial infection. In these cases, there is lymphohematogeneous spread, possibly through phagocytic cells loaded with viable yeast cells, with the patient developing the A/SAF characterized by disseminated involvement of the reticuloendothelial system (Franco *et al.*, 1987). In these patients, the lungs are usually spared, at least clinical and radiologically since autopsy and in vivo studies of A/SAC-like cases showed that the lungs can harbor yeast cells or very small subclinical or radiologically unapparent granulomatous inflammatory foci along the bronchial tree (Angulo-Ortega, 1972; Giraldo *et al.*, 1976; Restrepo *et al.*, 1989; Londero *et al.*, 1996; Buccheri *et al.*, 2015). It has been proposed that, based on the fact that A/SAF patients have profoundly depressed immune response against the fungus and loose granuloma formation, there would be little inflammatory-mediated tissue damage while such granulomas would not mature and evolve to dense fibrosis (Benard, 2008). This would explain the lack of residual fibrosis or other architectural abnormalities in patients with the A/SAF, for whom pulmonary involvement is probably restricted to the initial phase of the disease and remains underdiagnosed because of the absence of clinical or radiological evidence (Campos *et al.*, 1992; Benard *et al.*, 2005). Alternatively, witnessing the wide gamut of clinical presentations of the mycosis, some reports described A/SAF patients with a progressive primary pulmonary PCM much like that seen in tuberculosis: they developed simultaneously clinically overt pulmonary involvement and systemic reticuloendothelial involvement (Ramos *et al.*, 1981; Bittencourt *et al.*, 1986; Martinez and Moya, 2009).

Nevertheless it is roughly estimated that 98% of the infected individuals the quiescent foci, pulmonary or extra-pulmonary, remain so throughout life, making the rate of subclinical infections to outnumber many fold the (low) frequency of PCM disease even in endemic regions (Martinez, 2017). The most common clinical presentation of the disease is the CF, considered to result from fungal reactivation in these foci (Franco *et al.*, 1987). Thus, not infrequently the disease manifests when the patient has left

the endemic area. Of note these cases may manifest decades after leaving the endemic area, occasionally in patients living outside Latin America, when they represent an otherwise diagnostic challenge (Chikamori *et al.*, 1984; Silletti *et al.*, 1996; Horré *et al.*, 2002; Slevogt *et al.*, 2004; Kayser *et al.*, 2019).

In the chronic form, lung involvement frequently occurs. The mycosis is restricted to the lungs in some of these patients, but in most, other organs also are involved due to lymphohematogeneous dissemination from reactivated pulmonary foci or directly from foci at virtually any organ (Angulo-Ortega, 1972; Franco *et al.*, 1987; Benard *et al.*, 2013). Actually, PCM, in the A/SAF and CF, is almost always a disseminated disease, even though clinical manifestations are apparently restricted to a single organ: the degree of dissemination certainly is influenced by the availability of diagnostic procedures (Yamaga *et al.*, 2003; Shikanai-Yasuda *et al.*, 2017). After appropriate therapy, residual fibrotic lesions, remain in significant proportion of patients and represent the actual main challenge in the treatment of PCM (Mendes, 1994; Tabón *et al.*, 1995, 2003; Weber *et al.*, 2006; Costa *et al.*, 2013; Lopera *et al.*, 2015).

The time between infection and the onset of symptoms in the A/SAF of the disease is not precisely known, being estimated as weeks to many months; it lasted a few months according to the rare case reports with putative known date of infection (Franco *et al.*, 1987; Bучcheri *et al.*, 2015). On the other hand, the time elapsed between infection and the onset of symptoms in the CF is estimated as years to decades (Franco *et al.*, 1987).
